HALF-HOURS

WITH

THE MICROSCOPE;

BEING A POPULAR GUIDE TO THE USE OF THE MICROSCOPE

AS A MEANS OF AMUSEMENT AND INSTRUCTION.

BY EDWIN LANKESTER, M.D.

ILLUSTRATED FROM NATURE,

BY

TUFFEN WEST.

SECOND EDITION.

LONDON:

ROBERT HARDWICKE, 192, PICCADILLY,

AND ALL BOOKSELLERS.

710
1000
1000
1000

NOTICE TO SECOND EDITION.

THE design of this work is due to Mr. Hardwicke, who requested me to write the text, applying, at the same time, to Mr. Tuffen West to give him a series of illustrations. My time being so much occupied, I recommended Mr. Hardwicke to apply to a gentleman highly competent to execute the task. After some time, this gentleman was obliged, on account of other engagements, to relinquish it, and I then undertook to write an accompanying text to Mr. West's excellent plates. The work has been very favourably received by the public. I have only now consented to acknowledge my share in it, at the earnest request of the publisher, as I feel its chief merit is due to Mr. West's successful illustrations. In this edition I have corrected some trifling errors, and added some fresh matter, chiefly at the suggestion of Mr. West, Mr. Joshua Alder, and other friends.

E. LANKESTER.

APPENDIX.

THE PREPARATION AND MOUNTING OF OBJECTS	81
---	----

DESCRIPTION OF PLATES.

In the examination of these Plates the observer is requested to remember that they are not all drawn to the same scale. Some objects, adapted for low powers, are only magnified a few times, whilst smaller objects are magnified many hundred times. All objects, of course, vary in apparent size, according to the powers with which they are examined. Descriptions of the objects will be found in the pages indicated.

PLATE I. to face Title-page.

FIG.	PAGE
1. Vegetable cells with nucleus from apple	17
2. Cellular tissue from pith of elder	17
3. Stellate cell-tissue from rush	18
4. Flat tabular cell from surface of tongue.....	77
5. Ciliated cell from windpipe of calf	77
6. Human blood corpuscles	77
7. Blood corpuscles from fowl	78
8. Blood corpuscle from frog.....	78
9. Blood corpuscle from sole	70
10. Blood corpuscle from beetle	78
11. Filament of a species of <i>Zygnema</i> , a plant.....	46
a. Portion of a filament of the same, the cell- contents becoming changed into zoospores.	
b. Zoospore more highly magnified.	

FIG.	PAGE
12. Filament of a species of <i>Oscillatoria</i> , a plant	46
<i>a.</i> Portion more highly magnified.	
13. <i>Pandorina Morum</i> , a plant.	27-46
14. <i>Volvox Globator</i> , a plant	27-46
15. <i>Euglena viridis</i> , a plant, showing various forms which it assumes	47
16. <i>Amœba</i> , an infusory animalcule	44-55
<i>a, b, c</i> , show the various forms which this ani- malcule assumes.	
17. <i>Actinophrys Sol</i> , the sun animalcule	48-55
18. <i>Diffugia</i> , an infusory animalcule	49
19. <i>Arcella</i> , an infusory animalcule	49
20. <i>Lagena</i> , a species of Foraminifer	55
21. <i>Polystomella crista</i> , a species of Foraminifer.	55
22. <i>Globigerina</i> , a species of Foraminifer	55
23. <i>Rosalina</i> , from chalk, a Foraminifer	55
24. Living <i>Rosalina</i> , a Foraminifer	55
25. <i>Textilaria</i> , a species of Foraminifer.	55

PLATE II. to face page 16.

26. <i>Ulva</i> in different stages of development.	4
<i>a.</i> Cells in single series.	
<i>b.</i> Commencement of lateral extension.	
<i>c.</i> Portion expanded.	
27. <i>Cosmarium</i> , a species of Desmid undergoing self- division.	
28. <i>Euastrum</i> , a species of Desmid	48
29. <i>Closterium</i> , a species of Desmid	49
<i>a.</i> Undergoing self-division.	
30. <i>Desmidium</i> , a species of Desmid	49

FIG.	PAGE
31. <i>Pediastrum</i> , a species of Desmid.....	43
32. <i>Scenedesmus</i> , a species of Desmid.....	45
33. <i>Surirella nobilis</i> , a species of Diatom.....	45
34. <i>Pinnularia viridis</i> , a species of Diatom.....	45
35. <i>a. Navicula</i> , a species of Diatom undergoing self- division	
<i>b.</i> Front view of the same.	
36. <i>Melosira varians</i> , a species of Diatom.....	45
37. <i>Melosira nummuloides</i> undergoing self-division....	45
38. <i>Coscinodiscus eccentricus</i> , a species of Diatom.....	44
39. <i>Paramecium Aurelia</i> , an infusory animalcule.....	44
40. <i>Vorticella nebulifera</i> , an infusory animalcule.....	49
41. <i>Rotifer vulgaris</i> , a wheel animalcule.....	51
42. Stomates on a portion of cuticle of hyacinth leaf ..	18
43. Sinuous walled cells and stomates from under sur- face of leaf of water-cress.....	18
44. Cuticle of wheat straw with stomates.....	18
45. Cuticle from petal of geranium (<i>Peclargonium</i>)....	18 19
46. Cuticle from leaf of a species of aloe.....	19
47. Spiral vessel from leaf-stalk of garden rhubarb....	21
48. Ditto unrolled.....	21
49. Annular vessel from wheat root.....	21
50. Dichotomous spiral vessels.....	21
51. Dotted duct from common radish.....	21
52. Scalariform tissue from fern root.....	21
53. Woody fibre from elder.....	21

PLATE III. to face page 32.

FIG.	PAGE
54. "Glandular" woody tissue	18
55. Transverse section of glandular woody tissue	18
56. Transverse section of oak	19
57. Long section of oak	21
58. Oblique section of oak	21
59. Section of cork	21
60. Transverse section of coal.....	21
61. Longitudinal section of coal.....	22
62. Wheat starch	23
63. Oat starch	23
64. Potato starch	23
65. Tous-les-mois starch	23
66. Indian corn starch.....	24
67. Sago starch.....	24
68. Tapioca starch	24
69. Acicular raphides from garden hyacinth.....	24
70. Bundle of ditto from leaf of aloe contained in a cell	24
71. Compound raphides from stalk of garden rhubarb..	25
72. Tabular prismatic raphides from outer coat of onion	25
73. Circular crystalline mass from a cactus	26
74. Simple vegetable hair from leaf of a common grass	26
75. Rudimentary hair from flower of pansy	26
76. Simple club-shaped hair.....	26
77. Club-shaped hair from leaf of dock	26
78. Hair from throat of pansy.....	26
79, a. Hair formed of two cells from flower of white dead-nettle.....	27
79, b. Many-jointed tapering hair with nuclei from common groundsel.....	27

FIG.	PAGE
80. Beaded hair of sow-thistle.....	26
81. Glandular hair from leaf of common tobacco.....	27
82. Hair from leaf of garden chrysanthemum.....	27
83. Rosette-shaped glandular hair from flower of verbena.....	27
84. Stellate hairs from the hollyhock (<i>Althæa rosea</i>)..	27
85, <i>a</i> . Stellate hair from leaf of lavender.....	27
85, <i>b</i> . Hair from leaf of garden verbena, with warty surface.....	27
86. Hair from leaf of white poplar (<i>Populus alba</i>)	27
87. Base of a hair on a mass of cellular tissue.....	27
88, <i>a</i> . A sting from common nettle.....	27
88, <i>b</i> . Portion of a leaf of Valisneria.....	28

PLATE IV. to face page 40.

89. <i>Palmella cruenta</i> —gory dew.....	34
90. Yeast plant.....	34
91. Portions of vinegar plant.....	34
92. So-called cholera fungus obtained from the air....	34
93. Red rust of wheat.....	34
94. <i>Puccinia graminis</i> —mildew.....	34
95. <i>Penicillium glaucum</i> —common mould.....	35
96. <i>Botrytis</i> from mouldy grape.....	35
97. Fungus from mouldy bread (<i>Mucor Mucedo</i>)	33
98. Fungus from human ear.....	35
99. Fungus from leaf of bramble (<i>Phragmidium bulbosum</i>).....	35
100. Vine blight (<i>Oidium Tuckeri</i>).....	36
101. Potato blight (<i>Botrytis infestans</i>).....	36
102, <i>a</i> . Pea blight (<i>Erysiphe Pisi</i>).....	36
<i>b</i> . <i>Asci</i> and <i>sporidia</i> of pea blight.....	36
103. Fungus from a decayed Spanish nut.....	36

FIG.	PAGE
104. Curious fungus from oil casks	26
105. Fungus of common ringworm (<i>Achorion Schönleini</i>)	26
106. Fungus on stem of duckweed	26
<i>a.</i> Another within the cells.	
107, <i>a.</i> Branched cells from stem of mushroom.....	27
<i>b.</i> Branched cells from rootlets of mushroom	27
<i>c.</i> Reproductive bodies borne in fours on the gills of mushrooms.....	27
108. Section through a brilliant orange-coloured peziza	28
109. Section through the common yellow lichen of trees and walls.....	28
110. Leaf of <i>Sphagnum</i> —bog moss	28
111. Sea weed— <i>Polysiphonia fastigiata</i>	28
<i>a.</i> Fruit-bearing organs.	
<i>b.</i> Spore.	
<i>c.</i> Portion of Bisporë; and	
<i>d.</i> „ Tetraspore.	
<i>e.</i> Antheridia.	
112. Reproductive organs of a moss, a species of <i>Tortula</i>	28
<i>a.</i> The calyptra.	
<i>b.</i> The operculum.	
<i>c.</i> The peristome.	
<i>d.</i> The teeth.	
<i>e.</i> The spores.	
113. Fructification on back of frond of male fern.....	29
114. Fructification on back of frond of common brakes	29
115. Capsules of <i>Scolopendrium</i> — bartstongue. The sporules seen escaping	29
<i>a.</i> One of the latter more magnified	29
116. Fructification of <i>Equisetum</i> —horsetail	41
<i>a.</i> Shield-like disk of ditto, separated, surrounded by thecæ.....	41

FIG.	PAGE
116, <i>b</i> . Spore, much magnified, with elastic filaments coiled closely round	41
<i>c</i> . Spore expanded	41
117, <i>a</i> . Fructification of <i>Lycopodium</i> —club moss.....	40
<i>b</i> . Sporules	40
<i>c</i> . Sporules more highly magnified.	

PLATE V. to face page 48.

118. Delicate spiral cells from anthers of furze.....	29
119. Large well-developed spiral cells from anthers of hyacinth, with minute raphides in intercellular spaces	29
120. Irregular deposit in cells of anthers of white dead- nettle	29
121. Annular ducts from anthers of narcissus	29
122. Stellate cells from anthers of crown imperial	29
123. Ovate pollen cells.....	30
124. Triangular pollen cells from hazel	30
125. Pollen cells of heath	31
126. Pollen cells of dandelion.....	31
127. Pollen cells of passion flower	31
128. Pollen cells of mallow.....	31
129. Red poppy seed.....	31
130. Black mustard seed	32
131. Seed with deep and curved furrows	32
132. Great snapdragon seed	32
133. Chickweed seed.....	32
134. Umbelliferous seed or fruit	32
135. <i>Zygnema</i> , conjugating	46
136. <i>Closterium</i> , conjugating	43

FIG.	PAGE
137. <i>Cosmarium</i> , conjugating	43
138. <i>Epithemia gibba</i> , conjugating	43
139. <i>Mclosira nummuloides</i> , conjugating	43
140. Transverse section of common sponge	54
141. Transverse section of common British sponge	54
<i>a.</i> Spicules of the same more magnified.	
<i>b.</i> Calcareous spicules of <i>Grantia ciliata</i> .	
142. Pin-like spiculum from <i>Cliona</i> , a boring sponge ..	55
143. Spiculum from <i>Spongilla</i> , a fresh-water sponge ..	55
144. Spiculum from unknown sponge	55
145. Spiculum from <i>Tethea</i>	55
146. Common <i>Hydra</i>	56
<i>a.</i> Stinging organ from common <i>Hydra</i>	
147. A species of <i>Sertularia</i> , a zoophyte	57
148. <i>Campanularia integra</i> , a zoophyte.....	57
149. "Cup" of <i>Campanularia volubilis</i> , a zoophyte....	59
150. Spicula of <i>Gorgonia verrucosa</i>	59
151. Transverse section from base of spine of <i>Echinus</i> <i>neglectus</i>	58
152. Calcareous rosette from sucker of <i>Echinus</i>	58
153. Pedicellaria from <i>Echinus</i>	58
154. Pedicellaria from star-fish	58

PLATE VI. to face page 56.

155. <i>Lepralia</i> , a polyzoon	59
• 156. <i>Bowerbankia densa</i> , a polyzoon	59
157. Tobacco-pipe, or bird's-head processes of <i>Notamia</i>	59
<i>a.</i> Bird's-head process.	
158. <i>Bugula avicularia</i>	59
159. Bird's-head process of <i>Bugula Murrayana</i>	59

FIG.	PAGE
160. <i>Scrupularia scruposa</i> , with bird's-head processes (<i>avicularia</i>) and sweeping bristles (<i>vibracula</i>)..	59
161. Snake-headed zoophyte— <i>Anguinaria</i>	59
162. <i>Flustra foliacea</i> —sea mat	58
163. <i>Plumatella repens</i> , a fresh-water polyzoon.....	59
164. Egg of <i>Cristatella Mucedo</i> , a fresh-water polyzoon	60
165. Transverse section of shell of <i>Pinna</i> , showing prismatic shell structure	60
166. Longitudinal section of shell of <i>Pinna</i>	61
167. Transverse section from oyster-shell	61
168. Section of shell of <i>Anomia</i> , with tubular horns ..	61
169. Section of mother of pearl	61
170. Prawn-shell viewed as a transparent object	61
171. Teeth of whelk	62
172. Teeth of limpet	62
173. Teeth of periwinkle	62
174. Teeth of <i>Limncus</i>	62
175. Scale of sturgeon— <i>ganoid</i>	62
176. Prickle from back of skate— <i>placoid</i>	62
177. Borings by a minute parasite in a fossil fish-scale..	62
178. Scale of sole— <i>ctenoid</i>	63
179. Scale of whiting— <i>cycloid</i>	63
a. Calcareous particles, magnified.	
180. Scale of sprat— <i>cycloid</i>	63
181. Section of egg-shell	76
182. From soft egg.	
183. Section of egg-shell of emu.....	76

PLATE VII. to face page 64.

184. Human hair	5
a. Transverse section of human hair.	

FIG.	PAGE
185, <i>a.</i> Small mouse-hair	65
<i>b.</i> Larger mouse-hair.	
<i>c.</i> Plain mouse-hair.	
<i>d.</i> Minute hair from ear of mouse.	
186. Hair of long-eared bat.....	65
187. Transverse section of hair of peccary	66
188. Pith-like hair of musk-deer.....	66
189. Hair from tiger caterpillar	66
190, <i>a.</i> Branched hairs from leg of garden spider (<i>Epeira diadema</i>)	60
<i>b.</i> Spine, with spiral flutings, from the same.	
<i>c.</i> Small brush-like hairs from an Australian spider.	
191. Hair from flabellum of crab	67
192. Portion of four of the barbs of a goose-quill.....	67
193. Portion of the same more magnified	69
194. Swan's-down	67
195. Head and mouth of a flea	67
196. Head and mouth of a bug	67
197. Mandible of humble bee	68
198. Head and mouth of louse	68
199. Head and mouth of goat.....	68
200. Extremities of barbs of the sting of common bee..	68
201. Head of honey bee	69
<i>a.</i> Piece of the tongue more magnified.	
202. Mouth of blow-fly	70
203. Head and mouth of butterfly	70
204. One of the fangs of a spider, showing the poison- bag and duct	70
205. Foot of Empis, a species of fly	72
206. Foot of bee	73
207. Foot of spider	73

FIG.	PAGE
208. Head of common spider, showing eight simple eyes.	
<i>a.</i> Cornea of one of these more magnified.	71
209. Skin of garden spider	71
210. Portion of compound eye of fly	69
211. Portions of the two wings of bee in flight.	74
<i>a.</i> Nervule of wing.	
212. Spiracle of fly	72
213. Spiracle of <i>Dytiscus</i>	72
214. Threads of garden spider (<i>Epeira diadema</i>)	72
<i>a.</i> Simple thread of the same.	
<i>b.</i> Thread of a concentric circle with viscous dots.	

PLATE VIII. to face page 72.

215. Fore leg of <i>Gyrinus natator</i> , whirligig beetle	73
216. Middle leg of the same	73
217. Hind leg of same	73
218. Fore leg of male <i>Dytiscus</i>	73
219. Middle leg of the same.	
220, <i>a.</i> Gizzard of cockroach	73
<i>b.</i> Ditto, cut open.	
221, <i>a.</i> Gizzard of cricket	73
<i>b.</i> Ditto, cut open.	
222. Trachea from caterpillar	72
223. Proleg of caterpillar of common garden white butterfly, with the membranes in which the hooks are seated, expanded as in action	
224. Part of leg of cockroach	74
225. Battledore scale from blue argus butterfly	74
226. Scale of ordinary shape from same.	74
227. Scale from meadow-brown butterfly	74
228. Scale of gnat.	74

FIG.	PAGE
229. Scale reduced to a hair from clothes-moth.....	75
230. Hair-like scale from clothes-moth, with three prongs.....	75
231. Cartilage from mouse's ear.....	77
232. Transverse section of human bone.....	76
233. Striped muscular fibre from meat	73
234, <i>a.</i> Liber fibre of flax, natural state	65
<i>b.</i> Ditto, broken across at short intervals.	
235. Wool from flannel.....	65
236. Silk.....	64
237. Cotton hair	65
238. Crystal of honey	25
239. Thick crystal of ordinary sugar—sugar	25
240. Crystals of sugar from adulterated honey.....	25
241. Cuticle from berry of holly.....	19
242. Transverse section of whalebone	73
243. Transverse section of plum stone	17
244. Transverse section of testa of seed of Guelder rose	17
245. Fruit of groundsel—opaque	27
246. One hair of pappus of dandelion	27
247. Cottony hair of burdock	27
248. Portion of pappus of goat's-beard.....	26
249. Wood of young shoots of vine, the cells containing starch	19
250. Spiral fibres from testa of wild sage seed.....	20

HALF-HOURS WITH THE MICROSCOPE.

CHAPTER I.

A HALF-HOUR ON THE STRUCTURE OF THE MICROSCOPE.

THE Microscope is often regarded as merely a toy, and capable of affording only a certain amount of amusement. However much this might have been the case when its manufacture was less perfectly understood, it is now an instrument of so much importance, that scarcely any other can vie with it in the interest of its discoveries. By its means man increases the power of his vision, so that he thus gains a greater knowledge of the nature of all objects by which he is surrounded. What eyes would be to the man who is born blind, the Microscope is to the man who sees only with his naked eye. It opens a new world to him, and thousands of objects whose form and shape, and even existence, he could only imagine, can now be observed with accuracy.

Nor is this increase of knowledge without great advantages. Take for instance the study of plants and animals. These are endowed with what we call life: they grow and perform certain living functions; but as to the mode of their growth, and the way in which their functions were performed, little or nothing was known till the Microscope

revealed their minute structure, and showed how their various parts were related to each other. The Microscope has thus become a necessary instrument in the hands of the botanist, the physiologist, the zoologist, the anatomist, and the geologist.

Let us, then, endeavour to understand how it is this little instrument has been of so great service in helping on the advancement of science. Its use depends entirely on its assisting the human eye to see—to see more with its aid than it could possibly do without it. This it does in two ways: first by enabling the human eye to be brought more closely in contact with an object than it otherwise could be; and secondly by magnifying the object looked at.

Just in proportion as we bring our eyes close to objects, do we see more of them. Thus, if we look at a printed bill from the opposite side of a street, we can see the larger letters only; but if we go nearer we see the smaller letters, till at last we get to a point when we can see no more by getting closer. Now suppose there were letters printed on the bill so small that we could not see them with the naked eye, we could yet, by the aid of a lens—a piece of concave or convex glass,—bring our eyes nearer to the letters, and see. It would depend entirely on the form of the lens, as to how close we could bring our eyes to the print, and see; but this great fact will be observed, that the nearer we can get our eyes to the print, the more we shall see. The most important part of a Microscope, then, consists of a lens, by means of which the eye can be brought nearer to any object, and is thus enabled to see more of it. Magnifying-glasses and Simple Microscopes consist mainly of this one element. In order, however, to enable the eye to get as close as possible to an object, it becomes convenient to

use more than one lens in a glass through which we look. When these lenses are fixed in a brass frame, and attached to the Simple Microscope, when there are two lenses they are called doublets, and when three triplets. The magnifying-glasses which are made to be held in the hand, frequently have two or three glasses, by which their power may be increased or decreased. Such instruments as these were the first which were employed by microscopic observers; and it is a proof of the essential nature of this part of the Microscope, that many of the greatest discoveries have been made with the Simple Microscope.

The nearer the glass or lens is brought to an object, so as to enable the eye to see, the more of its details will be observed. So that when we use a glass which enables us to see within one inch of an object, we see much more than if we could bring it within only an inch and a half or two inches. So on, till we come to distances so small as the eighth, sixteenth, or even twentieth of an inch.

Although a great deal may be seen by a common hand-glass, such as may be purchased at an optician's for a few shillings, yet the hand is unsteady; and if these glasses were made with a very short focus, it would be almost impossible to use them. Besides, it is very desirable, in examining objects, to have both hands free. On these accounts the glasses, which in such an arrangement are called *object-glasses*, are attached to a *stand* and placed in an arm, which moves up and down with rack-work. In this way, the distance of the object from the glass can be regulated with great nicety. Underneath the glass, and attached to the same stand, is a little plate or framework, to hold objects, which are placed on a *slide* of glass. This is called *the stage*. Sometimes rack-work is added to this stage,

by which the objects can be moved upon it backwards and forwards, without being moved by the hand. Such an arrangement as this is called a *Simple Microscope*. Of course many other things may be added to it, to make it more convenient for observation ; but these are its essential parts.

But, although the Simple Microscope embraces the essential conditions of all Microscopes, and has, in the hands of competent observers, done so much for science, it is, nevertheless, going out of fashion, and giving way to the *Compound Microscope*. Although this instrument is much more complicated, as might be inferred from its name, than the Simple Microscope, it is now constructed with so much accuracy, that it can be used with as great certainty and ease as the Simple Microscope itself. In order to understand its construction, we must study the nature of the lens of which we have been speaking. If we take a lens, and hold it against an object on one side, and place a piece of white paper on the other side, we shall find that, at a certain point, a picture of the object will be produced on the paper. This is the way in which pictures are produced by the camera, of which the photographic artist avails himself for his portraits and sun-pictures. This picture of the object, then, exists in the air at a certain point beyond the lens. Now, this picture may be looked at by another glass, of the same character as the first ; and by this means the object is brought in a very enlarged form to the eye. Now, this is the principle involved in the Compound Microscope. In order to effect this object, a *tube* (generally of brass) is fitted to the object-glass, and at the upper part of this tube another lens is fitted on, called an *eye-piece*. The eye-piece consists generally of two lenses, the object of which is to bring the picture in the tube to a condition

in which it can be seen by the eye as readily as it could through the object-glass itself.

It is obvious that such an arrangement as this has great advantages over the Simple Microscope. In the first place, by the use of the lenses in the eye-piece, the object may be magnified to almost any extent. There is, however, a limit to the utility of this magnifying power ; for when objects are greatly magnified, they become indistinct. This is seen in the Oxyhydrogen and Solar Microscopes, where the images are thrown by means of highly magnifying lenses on a white sheet ; and, although made enormously large, their details are much less clear than when looked at by a lens magnifying much less. Another advantage of the Compound Microscope is the distance at which the eye is placed from the object, and the facility with which the hands may be used for all purposes of manipulation.

Compound Microscopes are generally fitted up with two eye-pieces, the one deep and the other shallow. The last has its lenses close together, and magnifies the most, whilst the other has them further apart, and magnifies less. In the use of these eye-pieces, it should never be forgotten that the one which magnifies least is generally the most trustworthy.

The Compound Microscope is now, undoubtedly, one of the most perfect instruments invented and used by man. In the case of all other instruments, the materials with which they are made, and the defects of construction, are drawbacks on their perfect working ; but, in the Compound Microscope, we have an instrument working up to the theory of its construction. It does actually all that could be expected from it, upon a correct theory of the principles upon which it is constructed. Neverthe-

less, this instrument did not come perfect from its inventor's hands. Its principles were understood by the earlier microscopic observers in the seventeenth and eighteenth centuries, but there were certain drawbacks to its use, which were not overcome till the commencement of the second quarter of the present century.

These drawbacks depended on the nature of the lenses used in its construction. The technical term for the defects alluded to are *chromatic* and *spherical aberration*. Most persons are acquainted with the fact that, when light passes through irregular pieces of cut glass—as the drops of a chandelier,—a variety of colours are produced. These colours, when formed by a prism, produce a coloured image called the *spectrum*. Now, all pieces of glass with irregular surfaces produce, more or less, the colours of the spectrum when light passes through them; and this is the case with the lenses which are used as object-glasses for Microscopes. In glasses of defective construction, every object looked at through them is coloured by the agency of this property. The greater the number of lenses used in a Microscope, the greater, of course, is the liability to this colouring. This is chromatic aberration; and the liability to it in the earlier-made Compound Microscopes was so great that it destroyed the value of the instrument for purposes of observation.

Again, the rays of light, when passing through convex lenses, do not fall—when they form a picture—all on the same plane; and therefore, instead of forming the object as presented, produce a picture of it that is bent and more or less distorted. This is spherical aberration, and a fault which was liable to be increased by the number of glasses, in the same way as chromatic aberration.

This defect, also, is increased in Compound Microscopes; and formerly, the two things operated so greatly to the prejudice of this instrument, that it was seldom or never used.

Gradually, however, means of improvement were discovered. These defects were rectified in telescopes; and at last a solution of all the difficulties that beset the path of the Microscope-maker was afforded by the discoveries of Mr. Joseph Jackson Lister, a gentleman engaged in business in London, who, in a paper published in the *Philosophical Transactions* for 1829, pointed out the way in which the Compound Microscope could be constructed free from chromatic and spherical aberration. This is done by such an arrangement of the lenses in the object-glass, that one lens corrects the defects of the other. Thus, in object-glasses of the highest power, as many as eight distinct lenses are combined. We have, first, a triplet composed of two plano-convex lenses, of crown-glass, with a plano-concave of flint-glass between them. Above this is placed a doublet, consisting of a double convex lens of crown, and a double concave one of flint-glass. At the back of this is a triplet, which consists of two double convex lenses of crown-glass, and a double concave one of flint placed between them. Such are the combinations necessary to correct the defects of lenses when employed in Compound Microscopes.

It is this instrument, then, which is most commonly employed at the present day, and to which we are indebted for most of the recent progress in microscopic observation. Its essential parts, in addition to those we have seen in the Simple Microscope, are the tube and the eye-piece. Its advantage over the simple instrument not only consists in its magnifying power, but also in the

facility with which it may be employed, in consequence of the more favourable distance the eye of the observer is from the object observed.

In using the Microscope, a great variety of accessory apparatus may be employed to facilitate the various objects which the observer has in view. As this is a book for beginners, we shall only mention a few of these.

Microscopes are generally supplied with small slips of glass, three inches long and one inch wide. These are intended to place the objects on, which are to be examined. They are either used temporarily or permanently with this object in view, and are called *slides*. When used temporarily, an object, such as a small insect, or part of an insect, is placed upon the middle of it; and it may be either placed immediately upon the stage at the proper distance from the object-glass, or a drop of water may be placed on the slide, and a piece of thinner glass placed over the object. This is the most convenient arrangement, as you may then tilt your Microscope without the slide or object falling off.

Objects, when placed under the Microscope, are of two kinds—either *transparent* or *opaque*. When they are opaque, they may either be placed upon the slips of glass, or put between a small pair of *forceps*, which are fixed to the stage of the Microscope, and the light of a window or lamp allowed to fall upon them. This is not, however, sufficient, generally, to examine things with great accuracy; and an instrument called a *condenser* is provided for this purpose. It consists merely of a large lens, which is sometimes fixed to the stage, or has a separate stand. Its object is to allow a concentrated ray of light to be thrown on the opaque object whilst under the object-glass of the Micro-

scope. This is called viewing objects by *reflected light*.

Transparent objects, on the other hand, are viewed by *transmitted light*: and here again the natural diffused light of day, or of a lamp, is not sufficient; so that all Microscopes are provided beneath the stage with a *mirror*, plane on one side and concave on the other. The object of this mirror, which is called the *reflector*, is to catch the rays of light and concentrate them on the object under the Microscope. The rays of light thus pass through the object, and its parts are seen much more clearly.

Another convenient piece of apparatus is an *animalcule-cage*. This consists of a little brass box, inverted, to the bottom of which is attached a piece of glass. Over this, again, is placed a lid or cover, with a glass top. The cover can be made to press on the glass beneath, and an object being placed between the two glasses, can be submitted to any amount of pressure thought necessary. This is a very important instrument for examining minute crustacea, animalcules, zoophytes, and other living and moving objects, especially when they live in water.

In the use of the cage and the slide, care must be taken not to break them, by turning the object-glass down upon them. The tube is provided with rack-work and a handle, by which it moves; so that the object-glass may be adjusted to any distance from the object. It is sometimes a difficult thing, when the object-glass has a focus of not more than a quarter or eighth of an inch, to adjust it to exactly the point at which the object is best seen, by means of the coarse handles on the rack-work; and to meet this case the Microscope is often provided with what is called a *fine adjust-*

ment, by which the object-glass is moved down on the object in a much slower and more gradual manner. Care, however, must always be taken lest the object-glass is brought down on to the object or slide, so as to break them. In some cases the lens of the object-glass itself has been broken in this way. Your incautious friends who have never seen a Microscope before, and have sufficient confidence in themselves to attempt to command a man-of-war, though they were in one for the first time, will frequently turn your Microscope up and down with a force sufficient to crack your lens. Such friends should, if possible, be kept from the table till the instrument is ready for them to take a peep, and then it is best to request that they will keep their hands behind them.

The picture of the object brought to the eye in the Compound Microscope is always the wrong end upwards. That is, the picture is always the reverse in the Microscope to what it is with the naked eye. You need constantly to be aware of this, especially if you are going to dissect an object under the Microscope, as your right hand becomes left, and your left right. The observer, however, soon gets accustomed to this, and it creates no difficulty ultimately. But science constantly attends on the Microscope, and ministers to its slightest defects. A little instrument called an *erector*, composed of a lens which reverses the picture once more, is supplied by the optician, and can be had by those who practise the refinements of microscopic observation.

Another instrument which will be found of considerable service even to the beginner with the Microscope, is a *micrometer*. This is an instrument for measuring the size of objects observed. Exag-

gerated notions about the smallness of objects are very prevalent; and as it is almost impossible to say accurately how small an object is without some means of measuring, a Micrometer becomes essential where accuracy is desired. This is effected by having some object of known size to compare with the object observed. The most convenient instrument of this kind is a glass slide, on which lines are drawn the hundredth and thousandth of an inch apart. If this slide, which is called a *stage micrometer*, is laid over an object, or the object placed upon it, its relation to the ruled lines will be easily seen, and the size computed accordingly. Many other forms of micrometer have been invented, but this is one of the simplest, and most easily used.

It is a good plan to make drawings of all objects examined, or at any rate those which are new to the observer. A note-book should be kept for this purpose, and what cannot at once be identified by the object, may afterwards be so by the drawing. All persons, however, have not the gift of drawing, and for those who need assistance in this way, the *camera lucida* has been invented. This instrument is applied to the tube of the Microscope when placed at right angles with the stem, in such a way that a person looking into it sees the object directly under his eye, so that he may easily draw its form on a piece of paper placed underneath.

Amongst the accessory apparatus are various arrangements for concentrating the light on the objects which are placed for examination under the Microscope. One of these combinations is called the *achromatic condenser*. This consists of a series of lenses, which are placed between the mirror and the stage, and which may consist of an ordinary object-glass. The stages of the larger

kinds of Microscopes are fitted up with a screw or slide, by which the condenser can be fastened beneath and adjusted to the proper focus for throwing light on the object examined. Instruments have also been invented, called *illuminators*, which are intended to supplement or assist the mirror in throwing light on the object. These are things, however, about which the beginner need not trouble himself. They are amongst the apparatus which contribute to the perfection of the Microscope, but are not amongst its necessary accompaniments.

The same may be said of the *polarizing apparatus*. The use of polarized light adds greatly to the beautiful appearance of many objects under the Microscope, but it is only in a very few instances in which it can be said to furnish a means of distinguishing one object from the other. It may, therefore, be left to the time when the observer has gone through some little practice with his instrument, and is inclined to buy the necessary apparatus.

Having said thus much with regard to apparatus, we will now give some directions for the use of the Microscope under ordinary circumstances. The Microscope may be either used by the light of the sun in the daytime, or at night by some form of artificial light. It is best used by daylight, as artificial light is likely to tire the eyes.

Having determined to work by daylight, some spot should be selected near a window, out of the direct light of the sun, in which to place a small, firm, steady table. On this the Microscope should be placed, and the object-glass should be screwed on to the tube. The mirror should be then adjusted so as to throw a bright ray of light on to the

object-glass. The eye-piece having been previously placed at the top of the tube, the Microscope is now ready to receive a transparent object. If the object to be examined is an animalcule, it may be conveyed to the animalcule-cage by means of a glass tube, called a *pipette* or *dipping tube*, which should be dipped into the water where the object is contained, with the finger covered over the upper orifice, so that no air can escape. By taking the finger off when the tube is in the water, the fluid will rush into the tube, and with it the object to be examined. The finger is again applied to the top of the tube, and the fluid obtained conveyed to the animalcule-cage: only such a quantity of the water should be allowed to fall out of the tube on to the cage as will enable the observer to put on the cover of the cage without pressing the fluid out at the sides of the cage. If the water is thus allowed to overflow, it runs over the glasses of the cage, and thus obscures vision. An object or objects having been thus placed in the cage, it is conveyed to the stage, and placed in such a position that the ray of light passing from the mirror to the object-glass may pass through it. This having been done, the observer must now place his eye over the eye-piece, and use the screw in the tube, and move the object-glass downwards until he gets a clear view of objects moving in the water. This is called *focussing*. The glass may then be moved up or down, in order that the best view of the object may be obtained. When the object-glass is one of high power, the *fine adjustment* may be used for this purpose. When the proper focus is obtained, the object may be moved up or down, right or left, with the hand, or by the aid of the screws which are employed in the various forms of what are called *moveable stages*.

When objects not requiring the live-box or animalcule-eage are to be observed, they may be transferred to the glass slide, by aid of a thin slip of wood, or a porcupine-quill moistened at the end, or by a pair of small *forceps*. Some transparent objects may be seen without any medium, but generally it is best to place them on the slide with a drop or two of clean water, which may be placed on it with a *dipping-tube*. When water is used, it will generally be found best to cover the object with a small piece of thin glass. Small square pieces of thin glass are sold at all the opticians' shops for this purpose. The object is then placed under the object-glass as before.

In order to render objects transparent, so that they may be viewed by transmitted light, very thin sections of them should be made. This may be effected by means of a very sharp scalpel, or a razor. When objects are too small to be held in the hand to be cut, they may be placed between two pieces of cork, and a section of them made at the same time that the cork is cut through.

Sometimes it is found desirable to unravel an object under the Microscope. If this is the case, only a low power should be used, and the object may be placed on a glass slide, without any glass over, and two needles with small wooden handles employed—ordinary sewing needles, with their eyes stuck in the handle of a hair-pencil, will answer very well. Even when dissection is not to be carried on under the Microscope, a pair of needles of this sort, for tearing minute structures in pieces, will be found very useful.

When opaque objects are to be examined, the light from the mirror may be shut off, and the aid of the bull's-eye condenser called in. The object being secured in the forceps attached to the stage

or laid upon a slide, the light is allowed to fall on it through the condenser. The object-glass must be focussed in the same manner as for transparent objects, till the best distance is secured for examining it. The petals of plants, the wings and other parts of insects, with many other objects, can only be examined in this way.

Even the beginner will find it useful to keep by him some little bottles, containing certain chemical re-agents. Thus, a *solution of iodine* is useful to apply to the tissues of plants, for the purpose of ascertaining the presence of starch. This solution may be made by adding five grains of iodine and five grains of iodide of potassium to an ounce of distilled water. Strong *sulphuric acid* will be found useful in rendering soft the tissues of both plants and animals ; and in conjunction with iodine it is a test for the presence of cellulose, the substance that forms the walls of the cells of plants. In order to apply this test, the tissue should be first touched with the sulphuric acid, and on the application afterwards of the solution of iodine the blue colour of starch becomes evident. The sulphuric acid has the power of converting the cellulose into starch.

The *strong solution of potash* (liquor potassæ) can also be employed with advantage in softening and making clear opaque animal and vegetable substances. *Nitric acid* has even a greater solvent power than sulphuric acid, and may be used for the same purposes. At the same time, the use of these powerful acids requires care, as, if they get on to the object-glass, or it is exposed long to the action of their vapours, its transparency may become impaired.

CHAPTER II.

A HALF-HOUR WITH THE MICROSCOPE
IN THE GARDEN.

AMONGST the objects which can be examined by the Microscope, none are more easily obtained than plants. All who have a Microscope may not be fortunate enough to have a garden ; but plants are easily obtained, and even the Londoner has access to an unbounded store in Covent Garden. We will, then, commence our microscopic studies with plants. On no department of nature has the Microscope thrown more light than on the structure of plants ; and we will endeavour to study these in such a manner as to show the importance of the discoveries that have been made by the aid of this instrument.

If we take, now, a portion of a plant, the thin section of an apple, or a portion of the coloured parts of a flower, or a section of a leaf, and place it, with a little water, on a glass slide under the Microscope, we shall see that these parts are composed of little roundish hollow bodies, sometimes pressed closely together, and sometimes loose, assuming very various shapes. These hollow bodies are called "cells," and we shall find that all parts of plants are built up of cells. Sometimes, however, they have so far lost their cellular shape that we cannot recognize it at all. Nevertheless, all the parts we see are formed out of cells. Cells tolerably round, and not pressed on each other, may be seen in most pulpy fruits. In fact, with a little care in making a thin section, and placing

it under the Microscope, the cellular structure of plants may be observed in all their soft parts.

If, now, we take a thin section from an apple, or other soft fruit, or from a growing bud, or tuberos root, as the turnip, we shall find that many of the cells contain in their interior a "nucleus," or central spot, a representation of which is seen from the cells of an apple in figure 1 of the first plate. This nucleus is a point of great importance in the history of the cell, for it has been found that the cell originates with it, and that all cells are either formed from a nucleus of this kind, or by the division of a thin membrane in the interior of the cell, which represents the nucleus, and is called a "primordial utricle."

When the cells of plants have thus originated, they either remain free or only slightly adherent to each other, or they press upon each other, assuming a variety of shapes; they then form what is called a "tissue." When cells are equally pressed on all sides, they form twelve-sided figures, which, when cut through, present hexagonal spaces. This may be seen in the pith of most plants, more especially the common elder, which is seen at figure 2 of plate 1. Transverse slices of the stems of any kind of plant from the garden may be made by a razor, or sharp penknife, and will afford interesting objects for the Microscope.

Cells, during their growth, assume a variety of shapes, and the tissues which they form are named accordingly. Two examples of such cells will be seen in figures 243 and 244 in plate 8, where the first represent cells from the hard shell of a plum stone, and the second the thin cells from the outside of the seed of the guelder rose. Sometimes the cells are very much elongated, or they unite together to form an elongated tube; the tissue thus formed is

called "vascular tissue ;" but where the cells retain their primitive form, it is called "cellular tissue." A very interesting form of the latter is the "stellate" tissue found in most water plants, and especially regularly developed in the common rush, a representation of which is given in figure 3 plate 1. The object of this tissue is, evidently, to allow of the existence of a large quantity of air in the spaces between the cells ; by which means the stem of the plant is lightened, and it is better adapted for growth in water.

If the leaf of any plant is examined, it will be found that on the external surface there is a thin layer, called, after the thin external membrane in animals, the "epidermis." This layer is composed of very minute cells—smaller than those in other parts of the plant, and when placed under the Microscope, presents a variety of forms of cellular tissue. The form of epidermal cells from various plants is seen in figure 42 and the following figures in plate 2. There is found in this layer a peculiar organ which exists on the outside of all parts of plants, and which demands attention. In the midst of the tissue, at very varying distances, are placed little openings, having a semilunar cell on each side. These openings are called "stomates," and can be well seen in the leaf of the hyacinth, which is shown in figure 42. where the cells of the epidermis are transparent : but the little cells which form the stomate are filled with green colouring-matter. The stomates vary very much in size and in numbers. They are found in larger numbers on the lower than on the upper side of leaves. In the common water-cress they are very small, as seen in figure 43. plate 2. and the cells of the epidermis are sinuous. The stomates are found on all plants having an epidermis.

In figures 44 and 46 they are represented from the wheat and the aloe. In the latter plant the cells of the cuticle are very much thickened. They can also be seen on the cuticle of the fruit, as shown from the holly in figure 211, plate 8, and also on the organs and petals. These form a beautiful object under the Microscope. The petal of the common scarlet geranium (*Pelargonium*) affords a beautiful instance of the way in which the cells of plants become marked, by their peculiar method of growth. This is illustrated in the cells of the common red-flowered geranium at figure 45, in plate 2.

The vascular tissue of plants is either plain or marked in its interior. If we examine the ribs of leaves, the green stems of plants, or a longitudinal section of wood, elongated fibres, lying side by side, are observed, as is seen in the case of the elder, at figure 53, plate 2. This is what is called "lignous" or "woody" tissue, and the greater part of the wood and solid parts of plants are composed of this tissue. Such tissue is seen upon the shoots of the young vine in figure 249, plate 8. The fibres mostly lie in bundles, and are divided from each other by cellular tissue. This latter, in the woody stems of trees, constitutes the "medullary rays," which are seen in transverse sections of stems, extending from the pith to the bark. The difference observable in the distribution of the woody fibres and the medullary rays renders the examination of transverse sections of the stems of plants a subject of much interest; figure 54 and the following figures in plate 3, present the appearances of thin sections of various kinds of wood (figures 54, 55, 56, 57, plate 3). In the transverse sections of stems of most plants, large open tubes are observed. This is seen in

the ease of the oak, figured at figure 55, plate 8. These are called "ducts." Such ducts may be well observed in the transverse section of the common radish, as seen at figure 51, plate 2, and in other roots. These ducts are often marked by pores, or dots, and are hence called "dotted ducts." These dots are the result of deposits in the interior of the tube of which the duct is formed, and a great variety of such markings are found in the interior of vascular tissue. One of the most common forms of marked vascular tissue is that which is called glandular woody tissue, of which a figure is given at 54, plate 3. This kind of tissue is found in all plants belonging to the cone-bearing, or fir tribe of plants. In order to discover it, recourse need not be had to the garden for growing plants, as every piece of furniture made of deal wood will afford a ready means of obtaining a specimen. All that is necessary to observe the little round disks with a black dot in the middle is to make a thin longitudinal section of a piece of deal, and place it under a half or quarter-inch object-glass, when they will be readily apparent. The application of a drop of water on the slide, or immersing them in Canada balsam, will bring out their structure better.

If we take the leaf-stalk of a strawberry, or of garden rhubarb, and make a transverse section all round, nearly to the centre of the stalk, the lower part will at last break off, but be still held to the upper by very delicate threads. If we examine these threads, we shall find that they are fibres which have been left by the breaking of the vessel in which they were contained: such fibres are seen at figure 48, plate 2. These vessels are called "spiral vessels," and are found in the stems and leaves of many plants. They are seen rolled up as

found in the garden rhubarb, at figure 47, plate 2. Sometimes these vessels are found branched, as in the common chickweed, which is seen at figure 50, plate 2. This arises from two spires coming in contact with each other, and adhering. Occasionally the spiral fibre breaks, or is absorbed at certain points, leaving only a circular portion in the form of a ring, as seen in a vessel from the root of wheat at figure 49, plate 2. Such vessels are called "annular," and may be observed in other roots besides those of growing wheat, as in the leaves of the garden rhubarb. A modification of this kind of tissue is seen in the stems and roots of ferns, in which the vessel assumes a many-sided form. This kind of tissue is called "scalariform," or ladder-like, and is seen in figure 52, plate 2. Sometimes the spiral fibre is free. This is represented at figure 250, plate 8, from the testa of the seed of the wild sage.

The bark as well as the wood of trees affords the same appearance under the Microscope. If a piece of the bark of any plant be examined by means of a very thin transparent section, and placed upon a slide, and put under an inch or a half-inch object-glass, the structure of the bark may be easily seen. On the outside of all is the cuticle, or epidermis, and under this lie two layers, composed, like the cuticle, of cellular tissue; but the inner layer, before we come to the wood of the stem, is composed of woody tissue. The cellular layer, next the woody one, is often developed to a very great extent, and then constitutes what we know by the name of cork. The bark from which corks are made is obtained from an oak tree which grows in the Levant. If we make a very thin section of a cork, its cellular structure can be easily made out. The cells are almost cubical, and when submitted to the

action of a little solution of caustic potash, they may frequently be seen to be slightly pitted. This is represented from cork in figure 59, plate 3.

Many of the structures which are described above may be seen in common coal; thus proving most satisfactorily that this substance has been formed from a decayed vegetation. A transverse and a longitudinal section of coal is shown at figures 60 and 61, plate 3. The examination of coal, however, is by no means an easy task, and the hands and fingers may be made very black, and the Microscope very dirty, without any evident structure being made out. Some kinds of coal are much better adapted for this purpose than others. Sections may be made by grinding, or coal may be submitted to the action of nitric acid till it is sufficiently soft to be cut. The amateur will not find it easy work to make sections of coal; but should he wish to try, he may fasten a piece on to a slip of glass with Canada balsam, and when it has become firmly fixed, he may rub it down on a fine stone till it is sufficiently thin to allow its structure to be seen under the Microscope. Coal presents both vascular and cellular tissue. The vascular tissue is, for the most part, of the glandular woody kind; thus leading to the inference that the greater portion of the vegetation that supplied the coal-beds belonged to the family of the firs.

The external forms of the tissues of plants having been examined, we are now prepared to regard their contents. In the interior of the cells forming the roots and the growing parts of plants will be observed a number of minute grains, generally of a roundish form. If we make a thin slice of a potato, these granules may be very obviously seen, lying in the interior of the cells of which the potato is composed, as seen at figure 64,

plate 3. If we now take a drop of the solution of iodine, and apply it to these cells full of granular contents, we shall find that the granules assume a deep-blue colour. This is the proof that they are starch; and as far as we at present know, no other substance but starch has the power of assuming this beautiful blue colour under the influence of iodine. We have thus a ready means at all times of distinguishing starch. The grains of starch are of various sizes and shapes. The starch of the flour of wheat has a round form, and varies in size; that of the oat is characterized by the small granules of starch adhering together in globular shapes. When these globules are broken up, the grains appear very irregular. Grains of wheat starch and oat starch are seen in figures 62 and 63, plate 3. In the arrow-root called "*Tous les Mois*," the grains of starch are the largest known, and, like those of the potato, they look as if composed of a series of plates laid one upon the other, gradually becoming smaller to the top. This is seen at figure 65, plate 3. These lines do not, however, indicate a series of plates, but appear more like a series of contractions of a hollow vesicle or bag. This vesicular appearance of starch may be made apparent by gently heating it, after moistening, over a spirit-lamp on a glass slide, or by dropping on it a drop of strong sulphuric acid. This action of the starch-granule appears to be due to the fact that the starch is converted into gum by the action of the heat on the sulphuric acid. Sago and tapioca are almost entirely composed of starch, and may be easily examined under the Microscope. Granules of sago are represented in figure 67, and those of tapioca at figure 68; they are readily distinguished by their size. The starch granules are insoluble in water, but they are easily diffused

through it ; so that by washing any vegetable tissue containing starch, with water, and pouring it off and allowing it to stand, the starch falls to the bottom. This may be done by bruising the vegetable tissue in a mortar, and then throwing it into cold water. The tissue falls to the bottom, and the starch is thus suspended in the water. In this way the various kinds of starches may be procured for microscopical examination. The granules of starch have frequently a little black irregular spot in their centre. In the starch of Indian corn it assumes the form of a cross, which is seen at figure 66, plate 3. Starch is a good object for the use of the polarizing apparatus, which can be applied to most compound Microscopes. The grains of starch, under the influence of polarized light, become coloured in a beautiful and peculiar manner, permitting of great variation, as in the case of all polarized objects.

If we take a little of the white juice from the common dandelion, and put it under the Microscope, we shall often see, besides the globules of caoutchouc which make the juice milky, crystals of various forms. Such crystals are called by the botanist "raphides,"—signifying their needle-like form. They arise from the formation and accumulation of insoluble salts in the fluids of the plant. They are seen in various plants, and under very different circumstances. Beautiful needle-like crystals can be seen in the juice of the common hyacinth, represented at figure 69 ; the juice may be obtained by pressing. A question has been raised as to whether they are always formed *in* the cell. They are mostly found lying in the cell, as in the leaves of the common aloe, seen at figure 70, plate 3 : they may also be found in the tissues of the common squill, and in the root of the iris. If a thin

section of the brown outer coat of the common onion is made, small prismatic crystals are observed. These are represented at figure 72, plate 3. Sometimes several of these crystals unite together around a central mass, forming a stellate body. These bodies have been called "crystal glands," but they have no glandular properties. They may be seen in the root and leafstalk of common rhubarb, and may be easily observed in a bit of rhubarb from a spring tart. From such a source, the drawing was made at figure 71. These crystals are mostly formed of oxalate of lime. They are constantly found in plants producing oxalic acid. The gritty nature of rhubarb root arises from the presence of oxalate of lime. Sometimes the oxalate of lime assumes a round dish-like form. Such forms are seen in plants belonging to the cactus family. A circular crystalline mass, as seen in a common cactus, is represented at figure 73.

Other substances, besides oxalate of lime, are found crystallized in the interior and on the surface of plants. Crystals of sulphate of lime have been found in the interior of cycadaceous plants. Carbonate of lime is found in crystals on the surface of some species of *Chara*, or stonewort. There is a shrub not uncommon in gardens, known by the name of *Deutzia scabra*, on the under surface of the leaves of which there are beautiful stellate crystals of silica. The best way of seeing these is to put the leaf under the Microscope, and to examine it by the aid of reflected light.

Sugar and honey assume a crystalline form, and may be known by the shape of their crystals. At figure 238, plate 8, a crystal of honey is represented; it is thinner and smaller than the crystal of cane sugar represented at figure 239. Honey is sometimes adulterated with sugar. Under these

circumstances the sugar crystal loses its definite outline, and assumes the form seen at figure 240.

The external surface of the parts of all plants will afford a rich field of amusement and instruction to the microscopic observer. The cuticle, or epidermis, of which we have before spoken, has a very varied structure, and contains the little openings (stomates) before described. The cuticle, which, in a large number of cases, is smooth, becomes elevated in some instances, and forms a series of projections, which, according to their form, are called "papillæ," "warts," "hairs," "glands," and "prickles." The papillæ are slight elevations, consisting of one, two, or more cells; the warts are larger and harder; whilst the hairs are long, the glands contain a secretion, and the prickles are hard and sharp. For examining the form and growth of these hairs, the flowers of the common pansy (heart's-ease) afford a good object. Some of the projections are merely papillæ, as in the case of the kind of rudimentary hair represented in figure 75, plate 3; others are found longer, and more like hairs, as seen in figure 76; whilst others are long, and, the sides of the hair having contracted, they assume the appearance of a knotted stick, as seen in the hair from the throat of the flower of the pansy, at figure 78. The family of grasses, wheat, barley, oats, and other forms, are favourable subjects for the examination of simple hairs, or hairs composed of a single elongated cell. At figure 74, a single hair is given from a common grass. All that is necessary to be done, in order to see these hairs, is to take any part of the plant where they are present, and to slice off a small portion with a sharp penknife or razor, and place it under the Microscope. They may be either examined dry, or a little water may be added, and a piece of thin

glass placed over them on the slide. Hairs are frequently formed of several cells. On the white dead-nettle the hairs are composed of two cells, as seen in figure 79*a*. The nucleus, or cytoblast, is often seen in these, and is represented in figures 76, 77, and 79, plate 3. On the common groundsel hairs may be seen, composed of several cells, each cell containing a nucleus, as at figure 79*b*. Hairs like a string of beads are found on the pimpernel and sow-thistle, which last will be found in figure 80, plate 3. Occasionally hairs become branched. Thus, on the leaf of the common chrysanthemum the hairs present the form of the letter T. This hair is represented at figure 82. On the under-surface of the leaves of the common hollyhoek hairs are seen with several branches, giving them a stellated appearance, as seen at figure 84. The common lavender is covered with stellate hairs, as seen at figure 85*a*. These hairs may be examined as opaque or transparent objects, when immersed in a little glycerine. The hair of the tobacco plant presents a peculiar knobbed appearance. The presence of these hairs is a test of the purity of tobacco. It is shown in figure 81. The verbona has rosette-shaped hairs, as in figure 83. Sometimes hairs are covered over with little dots, which are supposed to be deposited after the growth of the cells of the hair. Such hairs may be seen in the common verbona, and are represented at figure 85*b*. Hairs are sometimes loose and long, as in the white poplar, seen at figure 86. Occasionally an elevation, consisting of several cells, is formed at the base of a hair. These are shown in figure 87. When these cells contain a poisonous secretion, which is transmitted along the tube of the hair, the hair is called a glandular hair, or sting. Such are

the hairs of the common stinging-nettle, represented at figure 88a.

The hairs constituting the down or "pappus" of compositous plants assume a variety of forms. The seed or fruit of the common groundsel has a beautiful crown, given at figure 245, in plate 8. The pappus of the dandelion appears notched, as seen at figure 246. The burdock has a cottony hair, while the goatsbeard is like a feather,—both of which are represented respectively in figures 247b and 248.

If a hair is examined in its growing state, with an object-glass of one quarter of an inch focus, a movement of the particles in its interior is often observed. This is easily seen in the hairs around the stamens of the common Spiderwort (*Tradescantia Virginica*). Such movements are very common in the cells of water plants. One of those most commonly cultivated in aquavivaria at the present day, the *Valisneria spiralis*, affords the best example of this interesting phenomenon. In order to observe this movement, a growing leaf of the valisneria should be taken, and a longitudinal slice should be removed from its surface, by means of a sharp penknife or razor. The slice, or the sliced part left on the leaf, should now be put on a slide, a drop or two of water added, and covered with a thin piece of glass, when, after a little time, especially in a warm room, the movement will be observed. This movement takes place in the little particles around the sides of the cells represented in figure 88b, plate 3. It may also be seen in the leaves of the new water-weed (*Anacharis alsinastrum*), the frogbit, the rootlets of wheat, in the family of charas, and in the cells of many other water plants. In examining some species of *Chara*, the external bark, or rind, should be removed from

the cells, or the movements will not be seen. This movement seems dependent on the internal protoplasmic matter, or "primordial utricle," which is contained in many cells, and which, in these cases, is spread over the interior of the cell. It is, however, capable of contraction, and when the plants are exposed to cold, the utricles contract and prevent the movement of the contents in the interior. It is, apparently, the extension of this substance beyond the walls of the cell which constitutes the little hairlike organs called "cilia," which are constantly moving, and by the aid of which the spores of some plants effect rapid movements. Such organs are found in the *Pandorina Morum* and *Volvox globator*, moveable plants represented at figures 13 and 14, plate 1. The effect of these cilia in producing the movements of plants is well seen in the *Volvox globator*, which, on account of its rapid movements, was at one time regarded as an *animalcule*, but it is now regarded as a plant. Cilia are, however, more frequently met with in the animal kingdom. They are seen in the drawing of *Plumatella repens*, at *a*, in figure 163 of plate 6.

Amongst the parts of plants which can alone be investigated by the Microscope are the stamens. These organs are situated in the flower, between the petals and the pistil, and usually consist of a filament, or stalk, with a knob or anther at its top. If the anther is examined, it will usually be found to consist of two separate valves, or cases, in each of which is contained a quantity of powder, or dust, called "pollen." The walls of these valves are worth careful examination under the Microscope, on account of the beautifully-marked cellular tissue of which their inner walls consist. The cells of this tissue contain in their interior spiral fibres similar to those which have been described as present in

118
certain forms of vascular tissue. In the anthers of the common furze the fibres are well marked, and are represented in figure 128, plate 5; in the common hyacinth they are larger, and frequently present, in their intercellular spaces, bundles of raphides, as seen at Figure 119. In the white dead-nettle the fibre is irregularly deposited, as at figure 120. In the anthers of the narcissus, given at figure 121, the cells are almost vaseular in their structure, and present the same appearance as those described under the head of annular ducts. The reader should compare figure 121, plate 5, with figure 49, plate 2. In the crown imperial the fibres of the cells radiate from a central point in a stellate manner, as at figure 122.

When the anther-eases have been examined, a little of the dust may be shaken on to a slide, and examined as an opaque or a transparent object. Each species of plant produces its own peculiar form of pollen. These little grains are actual cells. They are the cells of plants which in their position in the anther will not grow any further. They are destined to be carried into the pistil, where, meeting with other cells, they furnish a stimulus to their growth, and the embryo, or young plant, is produced. The history of the development of these cells, as well as of those in the interior of the pistil, is a very interesting one, and is one of those subjects of investigation which has been created by the aid of the Microscope. The pollen grains vary in size as well as form. They are frequently oval, as seen in figure 123, plate 5. In the hazel and many of the grasses they are triangular. Those from the hazel are represented at figure 124. In the heath they are tri-lobed, as at figure 125; in the dandelion, and many of the compositous order of plants, they are beautifully sculptured, as seen

at figure 126. In the passion-flower, three rings are observed upon them, as though they had been formed with a turner's lathe—figured at 127. In the common mallow, they are covered all over with little sharp-pointed projections, like a hand-grenade. These are represented at figure 128. The microscopic observer should make himself acquainted with the forms of pollen grains, as, on account of their small size and lightness, they are blown about in all directions, and may be found on very different objects from those in which they have been produced. Some absurd mistakes have been committed by confounding pollen grains with other forms of organic matter. Thus, pollen grains in bread were regarded as bodies connected with the production of cholera.

The pistil, which is the central organ seated in the midst of the stamens in the flower of plants, will afford a great variety of interesting points for examination with the Microscope. In the earliest stages of the growth of the pistil, thin sections of it may be made, and the position of the ovules observed. In the ovule will be found the embryo sac, a central cell, which, on being brought in contact with the pollen grain, grows into the seed. The seed contains the embryo, or young plant. In most plants this is sufficiently large to be seen by the naked eye; but it may, nevertheless, be examined with advantage by a low microscopic power. The seed is covered on the outside with a membrane, which is called the "testa." This membrane is often curiously marked, and the whole seed may be examined as an opaque object with the low powers of the Microscope. In order to do this, the light must be shut off from the mirror, and, the object being placed on the stage, a pencil of light should be thrown upon it by the aid of the

bull's-eye condenser. If a seed of the red poppy be now examined, it will be found to have a uniform shape, and to be reticulated on its surface, as seen at figure 129, plate 5. The seed of the black mustard exhibits a surface apparently covered with a delicate network, seen at figure 130. Some seeds have deep and curved furrows on their surfaces, such as exhibited in figure 131. The great snapdragon has a seed covered with irregular projecting ridges, having a granuled appearance, represented at figure 132. The seed of the chick-weed presents a series of blunt projections, as in figure 133. In the various forms of umbel-bearing plants, the seeds adhere to the fruit, and the fruit is commonly called the "seed." Such are caraway, coriander, dill, and anise seeds. The plants of this family are very common weeds in our gardens and fields, and may be easily procured for microscopic examination. Some of these fruits are covered over with little hooks, seen at figure 134, whilst others present variously-formed ridges and furrows, which are amongst the best means for distinguishing these plants the one from the other.

PLATE 4

CHAPTER III.

A HALF-HOUR WITH THE MICROSCOPE
IN THE COUNTRY.

A Compound Microscope is not easily conveyed and put up in the fields, but the produce of the roads and waysides may be easily brought to the Microscope at home. No one who has a Microscope should walk out into the country without supplying himself with a few small boxes, a hand net, and three or four small bottles, in order to bring home objects for examination. The dry produce, which may be put into boxes, is of a different character from that which may be conveyed home in bottles. We shall, therefore, first direct attention to the minute forms of mosses, fungi, lichens, and ferns, which may be collected in boxes; premising, however, that many members of these families may be found without going into the country to seek for them. The cheese in the pantry, and the decayed parts of fruits, and objects covered with mould, are good subjects for microscopic examination.

Amongst the minuter plants and animals whose true nature can only be detected by the Microscope many are composed of a single cell, whilst others, like higher plants and animals, are formed by the union of a large number of cells. The greater proportion of the one-celled, or unicellular plants, as they are called, are found in water; but some are found on moist rocks, stones, and old walls. Amongst these there is one of exceedingly simple structure, called gory dew (*Palmella cruenta*). This

plant appears as a red stain upon the surface of damp objects. If a little of this red matter is scraped off the object to which it is attached, and placed under the Microscope, it will be found to consist of a number of separate minute cells, as represented at figure 89, plate 4. This plant belongs to the same family as the red-snow plant, and there are a number of forms of these minute organisms, which, on account of their rapid growth and red colour, have given rise to alarming apprehensions, in former times, when their true nature was imperfectly understood. One of them attacks bread, and gives to it the appearance of having been dipped in blood. They also attack potatoes. Of the same simple structure, but not having a red colour, is the yeast-plant, or fungus, shown at figure 90, plate 4. This plant abounds in yeast, and may also be found in porter and ale. If vinegar is allowed to stand for some time, a minute plant is developed, called the vinegar-plant. In its earlier stages of growth it exhibits elongated cells, looking like broken pieces of thread, seen at figure 91. Threads more fully developed are often seen in decomposing fluids, and upon the surface of decomposing animal and vegetable substances; such is the so-called cholera-fungus, which may be obtained by exposing damp slides to the air. They are shown at figure 92. Such plant-like threads can be collected from the air in damp and unwholesome cellars and rooms, and were at one time supposed to be connected with the production of that fearful disease, the cholera. It has been rendered, however, exceedingly probable that all these appearances are but different forms of the fungus which produces common mould, and which is known by the name of *Penicillium glaucum*. This fungus is represented

at figure 95. It may be found on the surface of preserves and jellies, and consists of a mass of filaments or threads serving as its base, from the surface of which individual filaments rise up, bearing a number of minute cells, which are the spores, or reproductive organs. These are seen at figure 96.

Plants such as these, and belonging to the family of fungi, are found everywhere on the leaves of plants in the summer and autumn, forming irregular spots, of a yellow, red, or black colour. If such leaves are brought home and placed under the Microscope, they present a never-failing source of interest. The red appearance on the leaves of wheat, called the rust, is due to one of these fungi, seen at figure 93, plate 4. This appears to be an early stage of the fungus, which produces what is called mildew, and is represented at figure 94. These fungi are so common on the wheat-plant that their spores mingle with the seeds when ground into flour, and can be found, when carefully sought for, in almost every piece of bread that is examined under the Microscope. Mouldy grapes, pears, apples, and other fruits, present fungi, having the same general form as that of common mould. Such a fungus is the *Botrytis* of mouldy grapes seen at figure 96. Mouldy bread also presents a fungus of this kind. This species is called *Mucor mucedo*, and is represented at figure 92. Its spores are arranged in a globular form. A fungus not unlike the last has been described as growing in the human ear, and is figured at 98. The leaves of the common bramble present a fungus in which the spores are arranged on a more dense and elongated head. This is called *Phragmidium bulbosum*, and is represented at figure 99. The *Oidium* which attends the blight of the vine, seen

at figure 100, and the *Botrytis* which accompanies the potato disease, figure 101, are other and interesting forms of these minute parasites. The common pea is subject to a blight which is accompanied by a peculiar fungus, seen at figure 102*a*, which, when examined by a low power, presents a globular mass, surrounded by minute filaments. Under a high power the central ball is resolved into a series of little cases, containing in their interior the minute spores. These are seen at figure 102*b*. Seeds, as well as fruits, are liable to the attacks of fungi during their decay. Figure 103, Plate 4, represents a fungus found in a mould upon a common Spanish nut. This fungus looks like a red powder spread over the surface of the nut. A fungus has been described as attacking the oil-casks in the London docks: its fibres resemble threads of black silk. It is represented at figure 104. The spores are found scattered about the fibres. As we have already seen, fungi are found on the human body, and accompany certain forms of disease of the skin, more especially those of the head. In these cases the fungi insert themselves into the follicle of the hair, and introduce themselves into its structure, so that it either falls off or becomes disorganized. The fungus of ring-worm, called *Achorion Schönleii*, is given at figure 105. If the seed of wheat is allowed to germinate in a damp place, the little rootlet which it sends down will be found covered over with a minute fungus. A fungus of some interest, on account of its unusual place of growth, may be found, in autumn, attached to the roots of the common duck-weed (*Lemna minor*), seen at figure 106 *a*, plate 4. In the same figure, at *b*, is represented a fungus of a different kind, it is parasitic within the cells, and has a bead-like

appearance. It may be an earlier stage of the growth of the former.

The microscopic structure of the higher forms of fungi is not without its interest. In the fungi a very elongated form of cellular tissue frequently occurs, and in the stem of the common mushroom it will be seen to be branched, as at figure 103. The looser portions of the fibres of the mushroom, which are found in the earth at the bottom of the stem, afford even a better illustration of this structure, and is given at figure 107. The gills of the mushroom, when put under the Microscope, display a number of small projections surmounted with four round cells; these are the spores arranged in fours, and which, on that account, are called *tetra-spores*. They are seen at *a*, figure 107.

In the woods, in winter time, fungi abound, and their parts may be examined under the Microscope with great interest. Amongst the winter beauties of the forest, none are more attractive than the various forms of peziza, or cup-moulds. If a section be made through one of the cups of these beautiful fungi, they will present the appearance drawn in figure 108, plate 4. A series of hollow elongated cases will be found lying between compressed elongated tissue. In these cases a series of rather oval minute cells will be found, which are the spores of the peziza. If these are magnified with a higher power, they will be seen to be covered over with minute spines, as seen at *a*.

Amongst the objects which more especially attract the attention of observers in the country, in winter time, are the various forms of lichens, which grow parasitic upon the bark of trees. There is one of a yellow colour, which spreads on palings and the barks of trees, like dried pieces of yellow paper. At the surface of the membranous scales of

which the plant is composed will be found deeper yellow spots. If one of these is cut through, and a thin section placed under the Microscope, it will be found to possess very similar organs to the peziza. A series of cases will be found, containing the minute spores by means of which the plant is reproduced. These cases, called *asci*, are figured at 109.

A walk across a damp uncultivated piece of ground will not fail to reveal some spots which are boggy. Here the bog-moss (*Sphagnum*) must be looked for, and when found, it may be regarded as a good illustration of the family of mosses, and portions preserved for microscopic examination. The leaves afford interesting examples of fibro-cellular tissue, as seen at figure 110; and this tissue may be examined from day to day, as affording an illustration of the process of development in vegetable tissue. Other forms of mosses may be found on banks, old walls, rocks, and crevices. The organs which produce the spores, or seeds, are well deserving the attention of the microscopic observer. These represent the pistils in the higher plants. The organs which represent the stamens are also very interesting, but they are not so easily procured. We therefore proceed to describe the spore-bearing organ. This may be easily seen with the naked eye, although its beauties cannot be brought fully out without the aid of the Microscope. The part which contains the spores is seated on a little stalk, and is called the "urn," and is represented in figure 112. Covering the urn, and fitting on to it like a nightcap, is the calyptra, marked *a*. On slipping off the calyptra, a conical body fitting into the urn is observed, and this is called the "operculum" (*b*). If the operculum is now lifted off, there is revealed, below, a series of

twisted hair-like threads (*c*), which are called the "peristome." These processes are held together by minute teeth (*d*). The spores (*e*) are found in the interior of the urn. All these parts are subject to great varieties in different kinds of mosses.

From the mosses we may pass on to the ferns. Like the mosses, they have no regular flowers, and the parts which correspond to the urns of the mosses are the small brown scaly-looking bodies seated on the back of the fronds, or leaves. In the male fern the little brown bodies which contain the spores are round, as seen in figure 113, and in the common brakes they are placed on the edge of the fronds, as at figure 114. These organs, which are called "sori," may be easily seen as opaque objects, under the lower powers of the Microscope. In the common hart's-tongue, or scolopendrium, the sori are arranged in elongated bands. In this case the sori are covered with a membrane called an "indusium." On opening this, the sori are found lying close together. Each one of these sori is found to be made up of a number of cases called capsules, or "thece," attached to a stalk by which they are fixed to the frond. This organ is seen at figure 115. These thece are beautiful objects under the Microscope. Springing from the top of the stalk is a series of cells which surround the case, forming what is called the "annulus." This ring possesses an elastic power; so that when it breaks, the capsule is torn open, and the spores in the inside escape. The spores are covered over with little spines, as at *a*, in the same figure. The spores of ferns are often called seeds, but they are more like buds than seeds. If one of these spores is watched during its growth, it will be found that it grows into a little green membranous expansion, on the surface of which the two sets of organs

resembling the pollen grains and ovules of the higher plants are developed. The representatives of the pollen grains are little moving bodies, resembling animalcules, which pass over the surface of the membranous expansion till they reach the ovules, or true spores of the fern, which they fertilize, and the young plant then shoots forth. The ferns, of which so many species may be found in a walk in the country, or cultivated in a Ward's case in town, are worthy the minute attention of the possessor of a Microscope, on account of the great variety of forms which their organs of fructification present.

The club-mosses are found on boggy moors and open places, and present a variety in the forms of their fructification. The reproductive organs are formed out of a transformed branch, and are found lying at the base of scale-like bodies, resembling the scales which form the fruit of firs and pine-trees, as seen at figure 115, *a*. The spores of the club-mosses are of two kinds, large and small; hence they are called "megaspores" and "microspores." The last are very minute, and when highly magnified, they present a reticulated appearance. The spores are seen at *b* and *c* in figure 117. In the interior of these spores is a minute worm-like body, which acts the part of the pollen in higher plants. The megaspores are much larger. They represent the spores of ferns, and produce an expanded membrane, on which grow the true representatives of the ovules, which coming in contact with the microspores, new plants are produced.

Another family of these flowerless plants, which has yielded highly interesting results to the microscopic observer is the group of horsetails. If these are gathered in the spring of the year, they will

117

present two forms ; one showing the leaves and green parts of the fruit ; the other, the leaves changed into reproductive organs. These may be very easily examined as opaque objects under the Microscope. The spores are seated on round shield-like disks, represented in plate 4, at figure 116, *a*. When the spores are examined by a higher power, they present four spiral filaments, which are twisted round the body of the spore, and seen at *b*. If the spore is breathed upon whilst under the Microscope, the spiral filaments gradually relax their grasp, and they become expanded and attached to the spore only at one end, as represented at *c*.

The study of the flowerless plants is one of never-ceasing interest. Within the last few years much has been done by the aid of the Microscope to clear away the mystery which surrounded the functions performed by certain organs they possess. Much more, however, remains to be done ; and an interesting field is still open to the inquiries of the microscopist. We will now, however, take our Microscope to the pond-side, where we shall still find many plants to interest us, belonging to the lower, or flowerless groups, together with animals, the companions of their aquatic life, and the representatives of their simpler mode of existence.

CHAPTER IV.

A HALF-HOUR WITH THE MICROSCOPE
AT THE POND-SIDE.

CISTERNS, ditches, ponds, and rivers, contain numerous objects to interest the microscopic observer. Some of these objects float on the surface of the water ; others are found swimming about in the midst of the water ; whilst the greater number are found at the bottom. In collecting objects from fresh water, little bottles may be used, and a common spoon or small net employed for collecting them. Where the objects are only few, large quantities of the water should be allowed to stand, and the whole poured off, with the exception of a table-spoonful or two, which may be then placed in a wine-glass. A little of the sediment may be taken up in a pipette or dipping-tube, and conveyed to the animalcule-cage, and the cover having been put on, it may be placed under the Microscope. If the objects are moving about too rapidly, the cover may be pressed down till they are secured. They may be first sought out with a low power, and when it is wished to examine them more closely, a higher power may be put on.

Of all the forms of microscopic plants which are found in fresh water, those belonging to the families of desmids and diatoms are most interesting. We have already spoken of plants consisting of one cell, and these also consist of one cell ; but they have this peculiarity, that their cells are divided into two equal parts, each part having the same form as the other. The desmids are dis-

tinguished from the diatoms by their bright-green colour, and by their cells not depositing siliceous matter, as is the case with the latter. The siliceous nature of the shells of diatoms is made apparent by their not being acted on by strong acids, as nitric and hydrochloric.

The desmids sometimes abound in ditches and small pieces of standing water. Amongst other objects in a drop of water they are easily recognized by their beautiful bilateral forms and dark-green colour. One of the most charming of these is named *Euastrum*, and consists of two notched halves of a bright-green colour, with darker green spots. It is represented at figure 28, plate 2. The green matter is composed of a waxy substance, called chlorophyle, and is the same matter as that which produces the green colour of leaves. Some of the desmids assume a lunate form, and are named *Closterium*, a species of which is figured at 29, plate 2. There are various species of *Closterium*, all of the same general form, and occasionally occurring in very great abundance. Sometimes several of the cells are attached together, forming a long chain, as in the genus *Desmidium*, seen at figure 30, from which the family takes its name. These break up and go on growing. When they grow, the new cells are formed between the two halves of the parent cells. This is represented at figures 136 and 137, plate 5. In a genus called *Scenedesmus*, several cells are united, and the two last halves are furnished with horns, as seen at figure 32; at other times several cells unite, forming a globular mass, as in *Pediastrum*, represented at figure 31. In this case each cell presents two projections, forming objects of singular beauty.

The diatoms are more numerous and widely

diffused than the desmids. The latter are decomposed, and their bodies perish when they die ; but from the fact that the diatoms deposit silex in their structure, they are almost imperishable. They are found in great abundance in the mud of rivers, ponds, and lakes. They are also present in those deposits of clay which once formed the bed of rivers and lakes, and which are now dry. In order to procure the diatoms from these deposits, the clay or earth should be well washed with pure water, and the deposit allowed to subside, and the water poured off. This may be repeated several times. The deposit is then to be washed with hydrochloric acid, and when the effervescence is over, the acid is poured off, and a fresh portion is added. This may be repeated several times, and when the hydrochloric acid ceases to act, nitric acid may be employed in the same manner. When no action occurs by its use cold, the deposit may be transferred to a watch-glass, and kept over a spirit-lamp, at a temperature of about 200° , for three or four hours. The deposit must then be well washed with pure water, to remove all the acid. The deposit will be found now to consist almost entirely of diatoms. If anything else be found, it will be grains of sand. By casting the deposit into a small quantity of water, and allowing the heaviest particles alone to subside, these will be generally found to contain the sand and larger diatoms. By repeating this process successively, the deposits consist gradually of smaller and smaller diatoms, which may be examined with gradually higher powers, in proportion to their minuteness. Some are perfectly round, as in the case of the genus *Coscinodiscus*, a species of which is figured at 38, plate 2. It is marked beautifully over their surface ; others are triangular ; some are

square, and attached together. The last form is seen in *Melosira*, species of which are figured at 36 and 37, plate 2, and 139, plate 5. The most common forms are those which are oval, or boat-shaped, and represented by species of *Pinnularia* and *Navicula* in figures 34 and 35 *a*, in plate 2. Some of these are again larger at one end than the other, as in *Surirella*, figure 33. The markings upon the surface are very various. In some forms the markings are exceedingly minute: so small are they, that certain species of diatoms have been used as test objects, for testing the highest powers of the Microscope.

Whilst living, the diatoms possess the power of moving about, and in some of them, as well as the desmids, a movement has been observed of the small particles in their interior. The diatoms are generally of a brownish or brownish-yellow colour, which seems to be due to a small quantity of iron in their composition. They are increased in the same way as the desmids, by the production of new cells between the parent frustules. This process is seen in figure 5, *a* and *b*, in plate 2. The continuance of the species in these organisms is secured by the process of conjugation and the subsequent formation of the spores. This process is exhibited in figures 133 and 136, plate 5. In some cases, however, the spore is found without the union of two cells, as in *Melosira* represented at figure 137, plate 5.

Sometimes, attached to the bottom of a pond or river, or growing from immersed objects, or floating about in the water, will be found long green filaments. These are the fronds of confervæ. All forms of these—and they are very numerous—will be found most beautiful objects for examination. They may be laid on a slip of glass in water, and

covered over with a piece of thin glass; or they may be placed in the animaleule-cage. They consist of a series of cells growing end to end, and their partition-walls can be easily seen. They are of a green colour, from the chlorophyle contained in their interior. In the case of the yoke-threads, the chlorophyle is frequently arranged in a spiral manner along the interior of the filament, as in the *Zygnema* represented at figure 11, plate 1. These yoke-threads may be often seen to unite with each other, and the contents of one cell are emptied into the other, forming the spore of the plant, as seen at figure 135, plate 5. The cell contents sometimes break up into smaller portions, called zoospores, which, when they escape from the cell in which they are contained, move about with great rapidity. This is seen in figure 11, plate 1, at *a* and *b*. The moving power of the lower planets is well seen in the division of these confervæ, called *Oscillatorias*, which are sometimes found in semi-putrid water. A species is figured at 12, plate 1. As they lie upon the glass slide they will be seen to move over each other in all directions: hence their name.

Some of the spores formed by the confervæ move about by the agency of little organs called cilia. These are extensions of the motile matter of the cell, and are found very commonly in the animal kingdom. Occasionally, a number of these ciliated spores are aggregated together, forming a rapidly-moving sphere. Of this the *Pandorina Morum* affords a good example, seen at figure 13, plate 1, in which each spore possesses two cilia. But the most remarkable of this kind of moving plant is the *Volvox globator*, represented in figure 14 of the same plate. This beautiful moving plant was at one time thought to be an animaleule, but it is now

regarded as a true plant. It consists of a large number of spores, or cells, each having two cilia, and connected together by a delicate network of threads. In the interior of this moving sphere are seen smaller globular masses, of a dark-green colour, which are the young of the volvox, which have not yet developed the network by means of which their spores are separated, and their ciliated ends presented to the water, and by means of which their movements are effected.

Another form which is now regarded as a locomotive plant is the *Euglena viridis*, seen at figure 15, plate 1. It is often found in prodigious numbers, giving to water the appearance of green-pea soup. When placed under the Microscope, it frequently presents a red speck, or point, at one end, and an elongated tail at the other. The red spot has been regarded as an eye; but if it is watched, it will be found the red colour will often extend from the red spot to the rest of the body; and it is probable that the red colour is only a change in the condition of the chlorophyle contained in its interior. Amongst this class of plants it is not unfrequent for the chlorophyle to assume a red colour at certain stages of its growth.

The transition from the filamentous to the membranous form of these plants is well seen in the species of *Ulvæ*. These are found in both fresh and sea water. In the early stages of its growth, the ulva presents the filamentous form of a conferva, as seen at *a*, in figure 26, plate 2. Gradually the cells of the filament split up into two or three seams (*b*); and this goes on till at last a broad flat membrane is produced (*c*).

If the plants of our fresh waters are interesting, not less so are the animalcules; for, just as we have one-celled plants so we have one-celled ani-

mals, and it was only by the aid of the Microscope that they were discovered and can be examined. Wherever the above plants are found, there will also be discovered animals to feed upon them. The animal is distinguished from the plant by its feeding on plants, whilst the latter feed on inorganic substances.

There is considerable difficulty in at once distinguishing between the lowest forms of animals and plants. Although the animal generally possesses a mouth, and a stomach in which to digest its vegetable food, there are some forms of animal life so simple as not to possess either of these organs. In the sediment from ponds and rivers there will frequently be found small irregular masses of living, moving matter. If these are watched, they will be found to move about and change their form constantly. As they press themselves slowly along, small portions of vegetable matter, or occasionally a diatom, mix, apparently, with their substance. Cells are produced in their interior, which bud off from the parent, and lead the same life. These creatures are called amæbas, and are represented in our first plate, figure 16. Although they have no mouth or stomach, they are referred to the animal kingdom. They appear to consist entirely of the formative matter found in the interior of all cells called moto planes or sarcode without any cell-wall. If we suppose an amæba to assume the form of a disk, and to send forth tentacles, or minute elongated processes from all sides, we should have the sun animalcule (*Actinophrys Sol*), which is represented at figure 17, plate 1. This curious creature has the power, apparently, of suddenly contracting its tentacles, and thus leaping about in the water. It can also contract its tentacles over particles of starch and

animalcules, and press them into the fleshy substance in its centre. This is undoubtedly an animal, but it has no mouth or stomach. A large number of such forms present themselves under the Microscope. Some of them are covered with an external envelope, which they make artificially, by attaching small stones and other substances to their external surface, as in the case of the *Difflugie*, seen at figure 18, plate 1; or they may form a regular case, or carapace, of cellulose, as in *Arcella*, represented at figure 19. We shall meet again with forms resembling these when we take our Microscope to the sea-side.

One of the most common animalcules met with in fresh water, and whose presence can easily be insured by steeping a few stalks of hay in a glass of water, is the bell-shaped animalcule. These animalcules, which are called *Vorticella*, are of various sizes. Some are so large that their presence can easily be detected by the naked eye, whilst others require the highest powers of the Microscope. They are all distinguished by having a little cup-shaped body, which is placed upon a long stalk, figured at 40, in our second plate. The stalk has the peculiar power of contracting in a spiral manner, which the creature does when anything disturbs it in the slightest manner. In some species these stalks are branched, so that hundreds of these creatures are found on a single stem, forming an exceedingly beautiful object with the Microscope. The stalks of these compound vorticellæ are contracted together, so that a large mass, expanding over the whole field of the Microscope, suddenly disappears, and, "like the baseless fabric of a vision, leave not a wreck behind." A little patience, however, and the fearful creatures will once more be seen to expand themselves in all their beauty.

The mouth of their little eup is surrounded by cilia, which are in constant movement ; and when examined minutely, they will be found to possess two apertures, through one of which currents of water pass into the body, and from the other pass out. Not unfrequently the eup breaks off its stalk. It then contracts its mouth, and proceeds to roll about free in the water. Many other curious changes in form and condition have been observed in these wonderful bell-shaped animaleules.

If, now, we go to a very dirty pond indeed, into which cesspools are emptied, and dead dogs and cats are thrown, we shall find abundant employment for our Microscope in the beautiful forms of animaleules which are placed by the Creator in these positions to clear away the dirt and filth, and prevent its destroying the life of higher animals. In such waters, amongst a host of minor forms, we are almost sure to meet with the magnificent *Paramecium Aurelia*, figured at 39, plate 2. He moves about the water a king amongst the smaller prey, on whom he feeds without ceasing. He is of an oblong form, covered all over with cilia, and very rapid and active in his movements, as able to dart backwards as forwards, and turning round with the greatest facility. In his inside several spots are observed. If a little indigo or earmine is introduced into the water in which he lives, these spots become coloured by his taking up these substances. From this, Ehrenberg concluded that these spots were stomachs, and as such spots are very common amongst these animaleules, he called them many-stomached (*Polygastrica*). There is, however, reason to doubt the correctness of this conclusion of the great microscopist, as, although these spots exist in the body, they are not necessarily stomachs. They are, in fact, empty spaces, or vacuoles in the

interior of the little fleshy lump of which the animal is composed. They are found in the vorticella, and in most of the true animalcules.

All animalcules have been called infusory, because they seem so abundant in many kinds of vegetable infusions. Ehrenberg divided them into *Polygastric* and *Rotiferous*. The last are also called wheel-animalcules, as, when looked at through the Microscope, they appear to be supplied with little wheels on the upper part of their body. The most common form of these creatures is the *Rotifer vulgaris*, represented at figure 41, plate 2. The branches or leaves of any of our common water-plants can scarcely be examined without some of those pretty little creatures being found nestling among them. The structure of these creatures is highly complicated, and the family to which it belongs is far removed from the polygastric animalcules with which it is associated by Ehrenberg. On examination, the wheels will be found to consist of two extended lobes, the edges of which are covered with cilia. These cilia are in a constant state of movement, and produce the appearance of wheels moving on an axis. Between the wheels is the entrance to the mouth, which, in many species of wheel-animalcules, is furnished with a strong pair of jaws. This leads to an œsophagus, a stomach, and an intestinal tube. Two little spots on the neck seem to indicate the existence of eyes; whilst a projecting organ, believed to be analogous to the antennæ, or feelers of insects, is seen directly below them. The tail is finished off with a pair of little nippers, by which the creature has the power of attaching itself to objects. When moving, its whole body is extended, but it has the power of drawing itself up like a telescope in its case, and appearing almost round.

The wheel-animalcules abound in our ponds and rivers, and sometimes occur in great numbers in the aquarium. They are very varied in their forms, and some of them possess great beauty. Several of them are fixed, forming on the outside of their bodies a little case or tube, in which they dwell.

CHAPTER V.

A HALF-HOUR WITH THE MICROSCOPE
AT THE SEA-SIDE.

ON a visit to the sea-side, the Microscope is an essential instrument to all who would wish to study the wonders of the ocean. It is a curious fact, that the few grains of common salt in the gallon of sea-water seem to determine the existence of thousands of plants and animals. We shall therefore find living in the sea-water, plants and animals belonging to the same families as those in fresh water, but belonging to entirely different species.

The sea-weeds present strikingly different forms. Although many of them are microscopie, and belong to the families of *Diatomaceæ* and *Confervaceæ*, all the larger forms present interesting objects for examination in the structure of their fruit-bearing organs. No better subject for the latter purpose can be procured than the common bladder-wrack, which is so abundant on all our shores. If a frond of this fuens is examined, there will be found at certain parts a swollen mass, dotted over with round yellowish bodies. If one of these is taken and carefully pressed between two pieces of glass, it will present the spores surrounded with hairs of the most delicate and various structure. Some of the spores are divided into four parts, and on this account are called tetraspores. These are seen at *d*, figure 111, plate 4. The bladder-wrack is frequently covered with minute parasites; one of the most common of these is *Polysiphonia fastigiata*,

which is represented at figure 111, plate 4. As seen in the drawing, this little plant is branched, and the stems present a series of flattened cells. On the branches are placed the fruit-bearing organs, in the form of little capsules, seen at *a*. These capsules contain tetraspores (*d*). At the ends of the branches are organs of another kind, representing the stamens, and which are called *antheridia*. These are seen at *e* in the same figure. The sea-weeds present a great variety in the form of these organs, and may be easily preserved for investigation in small glasses of sea-water.

The animal structures of the sea-water must now, however, claim our attention. Amongst the lowest form of animal life are the sponges. They are frequently cast on the shore with sea-weeds, and afford interesting objects for the Microscope. They are composed of animal matter, which lies upon a structure of horny, calcareous, or siliceous matter. The common sponge which is used for domestic purposes may be taken as a type of the whole group. If a thin section of the common sponge is made with a pair of sharp scissors and placed under a low power, it will be seen to be composed of a network of horny matter, represented in figure 140, plate 5. If now we take one of the common forms from our own sea-shore, we shall find that the network is composed of siliceous spicules lying one over the other, as represented in figure 141 of plate 5. If one of these spicules is examined (*a*) and compared with a spicule from another sponge, it will be found to differ in form and size; and the species of sponges can actually be made out by the shape of their spicules. Some of our British sponges have calcareous spicules. This is the case with *Grantia ciliata*. There is a little boring sponge, called

Cliona, found in the shells of old oysters, which has its spicules pin-shaped, as seen at figure 142. The fresh-water sponge has very peculiar-shaped spicula, and is represented at figure 143. In some the siliceous bodies are round, with projections, as in *Tethea*, seen in the drawing, figure 145. Sometimes the spicula assume a stellate form, and are even branched, as in the spicula of an unknown sponge given at figure 144.

Amongst the lowest forms of animal life, none are more interesting to the microscopic observer than those belonging to the family of *Foraminifera* (Hole-bearers). They are thus called on account of the minute holes which cover their shells. If we suppose a creature as simple in structure as the amœba, or sun animalcule, of which we have previously spoken, and which are figured in 16 and 17, plate 1, with the power of forming a little calcareous shell, we should have a foraminifer. Some of these shells have the form of a nautilus, and when first observed they were supposed to belong to this group of shell fishes. In form they certainly resemble the higher forms of mollusca, as may be observed in figures 20 and 22, in plate 1. Sometimes, however, they are elongated or cone-shaped, as in figure 21. Other forms are seen in figures 24 and 28. They may often be found alive at the sea-side, nestling in the roots of the gigantic tayles which are so often thrown on the shore after a storm. If the roots of these plants (*Laminariæ*) are washed, and the deposit examined carefully, the foraminifera will be seen at the bottom of the vessel, and may be picked out one by one. When this is done, they will be found to have the power of protruding through the little holes in their shells their soft bodies, in the form of long tentacles, as seen at figure 23, in the

first plate. With these they seem to have the power of moving, as well as of taking up the matters by which they are nourished. The shells of these creatures are not so small but they may be seen with the naked eye, and they need only a low power to observe all their structure. They are found at great depths in the ocean, and have been brought up by the dredge from the deepest parts of the Atlantic. They are very abundant in some rocks, especially in the chalk: they may be obtained from the latter substance by rubbing a piece of chalk with a brush in water. The water must be first decanted from the coarser particles of chalk, and in subsequent deposits the foraminifera will be found. They may be obtained from dry sand in which they are contained, by throwing the sand into water, when the sand will sink and the foraminifera will swim on the surface, and may be skimmed off. They are best examined as opaque objects.

The family of polyps will next command attention. One of the most simple forms of this family is found in ponds and rivers, and is called the fresh-water polyp or hydra. It is figured at 146, plate 5. It may be easily observed, adhering to plants, with the naked eye, and needs only a low power with transmitted light to observe it accurately. Its body is cup-shaped, surmounted with eight long tentacles, which it has the power of retracting. It produces young ones by the process of budding, and the buds may be often seen protruding from the side of their parents. It is very tenacious of life, and may be cut into several pieces, and each part will grow into a new hydra. These, with many other polyps and the jelly-fish, have their flesh filled with little hair-like bodies, which, from their property of stinging in some species, have

been called stinging hairs, as seen at *a*, figure 116. If we suppose several of these hydras placed in little cups upon a common branch or stem, we should have a *Sertularia*, or such an animal as is represented at Figure 145, Plate 2. These polyps are very common on all our sea-shores; and the branches and cups are often cast up on the shore, and regarded by the uneducated as sea-weeds. The branches and cups are called the *polypidoms* of the animal, and assume a great variety of forms. When the cups are fixed on ringed stalks, they constitute the genus *Campanularia*, seen at figure 148, plate 5. These cups are often objects of great beauty, as in those of *Campanularia volubilis*, figured in 149. It is the polypidom which constitutes the coral in the family of polyps, producing the masses of carbonate of lime which sometimes cover the bottom of the ocean and form reefs in the sea. In one family of polyps, known as sea-fans (*Gorgoniæ*), which are calcareous, the fleshy mass covering the horny polypidom contains spicula of various forms, which are beautiful objects under the Microscope. These spicula are seen at figure 150, plate 5. The red coral of commerce is another interesting form of these polypidoms. In some families of these polyps, as in the campanularidæ and the corynidæ, the young, before they arrive at their mature stage, assume the forms of minute medusæ or jelly-fishes. These are exceedingly beautiful objects for microscopic observation.

Another family of animals common enough in the sea, are the star-fishes and sea-eggs (*Echinodermata*). Although not themselves microscopic, certain parts of their structure present very interesting objects for examination. If a section is made of one of the spines of the common echinus, or sea egg, it presents under a low power a beau-

tifully radiated structure. This is seen at figure 151, plate 5. The suckers, also, of the same animal present little rosettes, surrounded by a very delicate hyaline disk, represented at figure 152. Upon the surfaces of both star-fishes and sea-eggs will be found little moveable bodies which are called *pedicellariæ*. In the sea-egg they possess three moveable nipper-like limbs, whilst in the common star-fish they present only two. These are represented at figures 153 and 154, plate 5. A controversy has been raised on the question as to whether these bodies are parasitic animals, or part and parcel of the structure of the creature on which they are found. As they are so constantly present, they are undoubtedly parts of the animal on which they are found. The movements of the nippers are very active, and they frequently lay hold of objects which pass near them.

As common on the shore as the polypidoms of the polyps, are the animal skeletons called, in some parts of the country, sea-mats (*Flustra foliacea*). When placed under a low power, and viewed by reflected light, the sea-mat is composed of little cavities or cells, seen at figure 162, plate 6. In each one of these is seated a creature of much more complicated organization than the polyps just examined. It has, it is true, a ring of tentacles; but if these are examined, the tentacles are found to be covered with cilia, as seen at *a*, in figure 163, plate 6. This family of creatures are called *Polysoa*, or *Bryozoa*, and form a group of animals which are classed with the *Mollusca*, or shell-fish. Sometimes these creatures attach themselves to sea-weeds, oysters, stones, and other objects at the bottom of the sea, forming a kind of cellular membranous expansion. Such are the species of *Leprælia*, figured at 155. Sometimes the cells are elongated

and elevated above the surface of the object on which they are placed, as in the case of *Bowerbankia*, seen at 156. A beautiful form of these creatures is the shepherd's-purse coral (*Notamia bursaria*), represented at figure 157. This creature belongs to a group of the polyzoa, remarkable for possessing little processes on the margins of their cells, in shape resembling the bowls of tobacco-pipes, birds' bills, and bristle-like organs. On examining them with the Microscope, they present a very complicated organization. The birds' bills possess two jaw-like processes, which open and shut like a bird's beak, and from this fact they have been called *avicularia*, or bird's-head processes (*a*). The tobacco-pipe form in *Notamia* is peculiar to that genus. In other species, as in *Bugula avicularia*, seen in figure 158, these creatures possess not only the bird's-head process, but a second, consisting of a long bristle or seta, attached by a joint to a process below (*b*). These bodies are called *vibracula*, and the bristle-like extremity is kept constantly in action, and the form of avicularia is seen in *Mergula Wenayana*, at figure 156. Both processes are seen in *Scupularia scruposa*, at figure 160. Few objects are more curious under the Microscope than these avicularia and vibracula in a state of action. Whilst the function of the vibracula, seen at *a*, figure 160, seems to be to sweep away objects that would interfere with the life of the animal in the cell, it has been suggested by some that the avicularia secure by their jaws the food necessary for its sustenance: it seems probable, however, that they serve the purpose of a protective police. Of the various forms which the cup itself assumes, none are more interesting than those of the snake-head zoophyte, shown at figure 161, plate 6, in which it assumes the form of a snake's head, with

the tentacula projecting like a many-parted tongue. The polyzoa are also inhabitants of the fresh water. Of these the most common form is the *Plumatella repens*, figured at 163. The eggs of a fresh-water species, *Cristatella mucedo*, seen in figure 164, are covered with projecting spines with double hooks at their extremities, perhaps for the purpose of catching hold of objects. Such eggs may be often found upon portions of water-lily, bulrush, and other aquatic plants which float about in our rivers, lakes, and ponds.

Although but few of the shell-fish belonging to the large class of mollusca are microscopic, yet the structure of their shells can only be investigated by the aid of the Microscope.

If any common shell be picked up on the sea-shore, it will be found to possess a rough outside, generally of a darker colour, and sometimes beautifully ornamented, whilst on the inside it is smooth, and frequently of a rose-colour. This inner smooth layer is called the *nacre* of the shell; and it is from this substance that pearls are formed in the interior of many shells. Both the outer and the inner layers present different kinds of structure in different species of shells. The outer layer can be well examined in the shell of the mollusc called the *Pinna*. The outer layer in this shell projects beyond the inner, and may be easily submitted to examination by reflected light under a low power, when it will exhibit the appearance represented at figure 166, plate 6. The external surface presents the appearance of hexagonal cellular tissue. If a portion of the shell is ground down, so as to form a very thin layer, it may be examined with transmitted light, and its hexagonal structure will be much more apparent. If a portion be examined lengthwise, it will be seen that the hexagons result

from the shell being composed of a series of hexagonal prisms, as seen in the view of a longitudinal section given at figure 166, plate 6.

All bivalve shells partake, more or less, of this character; and if a portion of the outer coating of the shell of the oyster be examined, it will be found to present a general resemblance to that of the shell of the pinna, as seen at figure 167. In many shells the inner layer is almost structureless, but in those cases where the smooth white appearance is presented which is called *mother-of-pearl*, it consists of a series of waved laminae lying irregularly one on the top of the other; represented at figure 169. In other shells this membranous internal layer is traversed by minute tubes, as is seen in the genus *Anomia*, seen at figure 168. This structure has been considered due to the natural form of the shell; but late investigations lead to the conclusion that these tubules are the borings of some parasitic animal.

The shells of the crustacea also present a series of very interesting structural differences. The shell of the common prawn, when mounted in Canada balsam, or examined in water or glycerine, presents a series of bodies looking like nucleated cells. These are seen in figure 170, plate 6. Many shells present this appearance, and it was at one time supposed to indicate clearly that the shell originates in cell-growth as well as other parts of the structure of an animal. It has been, however, recently shown, that such appearances as that presented by the prawn-shell may be produced by the crystallization of inorganic salts in contact with organic substances in solution, independent of a living organism.

Surprising as it may seem to some persons, the teeth of mollusca afford beautiful objects for mi-

microscopic examination. All that is necessary to examine these organs is, to take the palate, or tongue, as it is called, of any of our common molluscs, and to stretch it on a glass slide, when it may be seen by transmitted or reflected light. In the common whelk, the teeth are placed in rows, and are composed of a broad base with four projecting points, the two outer of which are larger than the inner, as seen in figure 171, plate 6. In the limpet, the teeth present four projections, which are all of the same size ; seen in figure 172. In the common periwinkle another kind of arrangement is observed, and is figured at 173.

When sea-side specimens have been observed and put up, the fresh-water mollusca may be next investigated. Here other forms will be observed. The species of the genus *Limneus* are found in every pond, and kept in every aquarium. The tongues of these creatures, represented at figure 174, will give a lively idea of the nature of the scavenging processes they carry on.

The scales of fishes are interesting microscopic objects. The structure of these organs indicates the family of fishes to which they belong. It is in this way that a single scale found in a rock will throw a light on the nature of the fishes which inhabited the seas or rivers from which the rock was deposited.

Fishes' scales have been called *ganoid*, *placoid*, *cycloid*, and *ctenoid*, according to the families to which they belong. The sturgeon has *ganoid* scales. They are shiny, and have a structure like bone, and are represented at figure 175, plate 6.

The sharks, rays, and skates have *placoid* scales. They are frequently terminated with a prickle, as in the scales of the skate ; seen at figure 176.

This structure resembles the tubular structure in the teeth of the higher animals.

Fish-scales are frequently permeated with minute tubes, drawn in figure 177, plate 6. These appear to be the work of some minute parasite, such as that producing the tubules in shells, and which has hitherto evaded the scrutinizing investigation of the microscopic observer.

The fishes of the earlier rocks belong to the *ganoid* and *placoid* groups. The great majority of recent fishes belong to the remaining groups. The common sole affords an instance of the *ctenoid*, or comb-like scale, seen at figure 178.

The *cycloid*, or circular scales, are found in such fish as the whiting, and represented at figure 179. It is not uncommon to find in these scales calcareous particles, shown at *a*. In the sprat the *cycloid* scale assumes a form almost as broad as it is long, and is seen in figure 180.

The examination of these hard structures in the marine creatures is a good preparation for the further study of those hard parts in the higher animals to which the name of bone and ivory is given. Such things may, however, be procured in the house; and when the rain is falling, the sea-side forsaken, or the country miserable-looking, we can still enjoy the long winter evenings with our Microscope in the house.

CHAPTER VI.

A HALF-HOUR WITH THE MICROSCOPE
IN-DOORS.

FOR amusement and instruction with the Microscope, we need scarcely stir out of our rooms. The very hairs on our head may be made objects of interesting investigation, and especially if we compare them with the hairs of other animals, and the appendages generally of the skin. The fine outer coating of the skin is composed of minute scales, which are flattened cells, and may be easily observed by scraping a portion of the skin on to a glass slide with a drop of water on it. The nails, the hairs, and other appendages of the skin, are composed of the same kind of scales, or cells. These cells are developed in little pits, or follicles, from which the hair is projected, as it were, by their growth from below. Under a low power the cells of the human hair cannot be observed. It presents, however, a well-marked distinction between the outside, or *cortical layer*, and the interior, or *pulp*. The latter, by a high power, especially if the hair has been first submitted to the action of sulphuric acid, will be found to contain cells more or less spherical, whilst the former contains cells more or less flattened. These project a little beyond the edge of the hair, so that its sides are not quite smooth, as seen at figure 184 in plate 7. By placing a hair between two pieces of cork, fine transverse sections of it may be made by means of a sharp razor. If these are put under the Micro-

scope, the pulpy portions will present a dark appearance in the centre, as seen at *a*. The hairs of animals offer a great variety in the disposition of the cells of which they are composed. The hairs of the mouse present a series of dark partitions running across the hair between the cells. In the younger hairs, these partitions are single, as represented at *a* in figure 185, plate 7; whilst in the older ones they appear double, as seen at *b*. The hairs from the ear of the mouse present these dark partitions very distinctly, shown at *d*. Such hairs stand intermediate between true hair, a section of which is seen at *c*, and wool. A piece of flannel or blanket will afford a good illustration of the latter. This is figured at 235 in the 8th plate. In this case it will be seen that the scales, or cells, of the cortical part, project beyond the surface, and render the wool rough. This roughness of the outside is supposed to render such hairs fitted to be used in the process of felting; the rough sides of the hairs adhering together. The chemical composition of the hair has also something to do with this process. Human and other smooth hairs, will not felt.

The fibres of plants used in weaving may be conveniently compared with hairs derived from the animal kingdom. The woody fibre of the flax may be obtained from a linen handkerchief. A linen fibre is represented at *b* in figure 234, plate 8. The apparent knots in the fibre arise from injury in the uses to which the fabric has been applied. The original fibres have no such fractures, as shown at *a*, and are perfectly smooth. So are the fibres of silk, represented at figure 236. Cotton-wool is produced from the inner surface of the pod, or fruit of the cotton-plant, and is figured at figure 237. It becomes twisted during its growth, and although

not so strong as linen or silk, its irregular surfaces permit its being spun into a strong yarn, from which all cotton fabrics are made. The young microscopist should make himself acquainted with the forms of these various fibres; as, from their being so constantly present in rooms where the Microscope is used, and occasionally employed in cleaning the apparatus, they often present themselves as foreign substances, among other objects that are being examined.

It is also interesting, and sometimes of importance, to be able to ascertain of what material a fabric may be composed. Thus by means of the Microscope, and that alone, we know certainly that the cere-cloths in which Egyptian mummies are wrapped is a linen fabric, whilst the similar investment of Peruvian mummies is cotton. The hair of the bat, represented at figure 186, plate 7, presents a singular instance of the projection of the scales, or cells, in a regular form. Hairs are not often perfectly round;—in the peccary they are oval, as seen in figure 187, plate 7. If a transverse section of this hair is examined, it will be found that the cortical substance projects completely into the pulpy part of the hair in several places, so as to break up the pulp into several separate sections.

In some cases it is not easy to distinguish between outside and inside structure, as seen in the hair of the musk-deer, in which the whole is found to consist of a mass of hexagonal cellular tissue, similar to that seen in the pith of plants. This hair is shown in plate 7, figure 188.

Insects are frequently covered with hairs, especially in their larva, or caterpillar state. These hairs when stiff and sharp, penetrate the skin, and produce irritation there. This is the case with the large tiger caterpillar. The hairs of this cater-

pillar are furnished with a series of barbs, which, when they once penetrate the skin, are not easily removed, as seen in figure 189, plate 7.

Spiders are frequently covered with hairs, some of which are branched, as at *a* in figure 190; others present a spiral appearance, seen at *b*; whilst, again, others offer a series of small bristle-like hairs running down each side of the primitive hair, which will be seen at *c*.

Many of the crustacea have hairs upon their shells. Those upon the flabellum of the common crab have minute bristles on one side of the parent stalk, so as to form a little comb, with which to brush off the impurities from its branchiæ. This structure is seen at figure 191 in plate 7. A live crab from the aquarium may be watched for the purpose of observing these cleanly movements.

The study of the uses of the epidermal appendages is one full of interest, as in no one set of structures do we find a greater variety of adaptations of a common plan to the wants of the creatures in which they are found. The feathers of birds belong to the same type of structure as the hairs of animals. If the pinnæ of a common goose-quill, used for a pen, are examined, the pinnules will be found to be covered with minute hooks, drawn in figures 192 and 193, plate 7. These hooks on the upper surface are so arranged that they catch the nearly plain and slightly toothed pinnules on the lower side.

The down from the feathers of the swan, with which pillows and beds are stuffed, is also a beautiful object, and its microscopic structure will at once reveal the cause of its lightness, softness, and warmth. This is seen at figure 194, in the 7th plate.

Amongst the creatures which domesticate with

us are certain insects which are more frequently discovered than acknowledged. However disagreeable their presence may be, they become interesting objects for microscopic investigations, and are not less calculated to excite our admiration than creatures more ceremoniously treated. We first call attention to the common flea (*Pulex irritans*). This beautiful insect belongs to a large family, each species of which has its peculiar habitat in the epidermal appendages of some of the higher animals. The head of the human flea may be taken as the type of the family. This is represented with great accuracy at figure 195, in plate 7. It is furnished with antennæ, mandibles, and a pair of lancet-shaped jaws, with which it makes little wounds in the skin, and into which it pours the irritating secretion which renders its bite a source of annoyance. Its eye, large hind legs, and ornamental saddle on its back, are all deserving of attention.

Let us now seek another too common inhabitant of London houses, the bed-bug (*Cimex lectularis*), and, having decapitated him, submit his head to a low power. He, too, is a biting creature ; and you will observe, as drawn in figure 196, that his jaws are finer than those of the flea, and are like a pair of excessively fine sharp hairs ; they are inclosed in a sheath, from whence they are projected when used. In the same sheath is the tongue, which performs the double office of depositing in the wound an acrid and irritating secretion and sucking up the blood of its victim. The antennæ and eyes of the bug are also worthy of examination. From the latter will be found projecting minute hairs.

A still more despised animal may now be sought (*Pediculus*). It also belongs to a large family, and

each mammal and bird seems to be attended with its peculiar louse. Two species are found in dirty and diseased conditions of the human body. Disgusting as connected with want of cleanliness, they are, nevertheless, perfectly harmless. The head and mouth, drawn in figure 198, indicate that these creatures are adapted to live on the secretions of the skin. The above animals all belong to the much larger group of creatures adapted to live as parasites upon other animals.

The head of the common gnat, figured at 199, in plate 7, may be now examined for the sake of comparison. In this creature, the eye of the insect may be studied. It is what is called a *compound* eye, and is composed of innumerable small lenses; each one of which is connected with a twig of the optic nerve, and capable of receiving impressions from external objects. The little lenses terminate on the convex surface of the eye, presenting an immense number of hexagonal facets. These are seen at figure 210, plate 7. In the common house-fly, there are said to be 4,000 of these facets; and in the cabbage-butterfly 17,000. The antennæ of the gnat are very beautiful; and, in fact, these organs in insects afford an endless variety of forms. At their base, in the gnat, is seen a round process on which these are seated, and it has been supposed that they are organs of hearing. Whether they are organs of hearing or not, it is very certain that they are organs of touch, and the creature is very susceptible of the slightest stimulus applied to them.

The head of the honey-bee may be now examined; and if a careful dissection is made of its mouth, a marvellous apparatus is unfolded to view, which is exhibited in figure 201, plate 7. At the base is seated the so-called *mentum*, and on each side are

placed the *mandibles*; above these, and longer, are the *maxillæ*, and on each side of the prolonged central organ, called the tongue, are placed the labial palpi. The tongue can be retracted between the palpi as into a sheath. It is marked by a series of annular divisions, and, by a high power, will be seen to be covered over with hairs. This is the organ by means of which the bee "gathers honey all the day."

Whilst examining the bee, its sting may be taken out and placed under a low power, when it will be found to present the appearance of a pair of spears set with recurved barbs, which run part of the way down one side of each half of the sting. This is seen in the 7th plate, figure 200. Each of these spears is grooved on the opposite side, the two, when united, forming a canal, down which are poured the contents of the poison-bag, producing the painful effects of wounds from these instruments.

To return to the head and mouth of insects:—The tongue of the bee may now be compared with the same organ in the butterflies, which in them assumes the form of a proboscis, and is called the *haustellum*, seen at figure 203, plate 7. This instrument is coiled up when the insect is at rest, and is the organ by means of which the creature sucks up its nutriment from the flower. It has a series of lines running across it.

If the head of the common blowfly be now examined, it will be seen that the tongue, instead of being elongated as in the latter instances, is expanded laterally. This is represented in figure 202, plate 7. It is a very beautiful object, and when viewed by transmitted light, a series of spiral bands are observed to wind across each half of the tongue.

The head of the common garden spider (*Eperia diadema*) presents an interesting development of the mandibles. These organs are in pairs; each mandible consists of two joints: one is small, sharp, and hooked; whilst the other is large and short, and contains within it a bag, or poison-gland; so that when the creature seizes its prey, the bag is pressed on, and a drop of the poison exudes. This organ is represented in figure 204, plate 7. This structure is similar to what is met with in the poisonous serpents, where a poison-bag is seated at the base of a tubular tooth.

The description above given is the generally received one; but Mr. John Blackwall, our greatest authority on spiders, considers the use of the term "mandibles" to parts entirely without the mouth objectionable; he has accordingly bestowed the name of "falces" upon them. Some carefully-conducted and interesting experiments of his on their so-called poisonous secretion seem to throw great doubts on the propriety of regarding them in this light, and he has been led to consider that the purposes of it may rather be to deaden pain and still the struggles of a captured animal, as chloroform is given previous to and during operations on human beings.

The head of the spider affords also a good example of what are called *simple* eyes. Besides the compound ones before mentioned, insects have also these simple eyes—drawn at figure 208, plate 7. They consist of a single lens, as seen at *a*, and are placed in various positions in the heads of spiders.

The skin of the common garden spider is covered with hairs. These appear to surmount a series of concentric plates, seen at figure 209, plate 7. They vary in form in different species of spider;

and the skin of all should be examined for the purpose of observing these differences. The web of the spider should also be examined. The cords of these beautiful structures, which run from the centre to the circumference of the web, are plain, as seen at figure 214; whilst those which form the concentric lines are beaded with drops of a glutinous substance. It is by means of this adhesive matter that the webs are held together. Nor should the microscopist neglect examining the spinnarets of the spider, by which these beautiful threads are elaborated.

The breathing organs of insects are well deserving attention. Their bodies are perforated at the sides, and the openings thus formed, called *spiracles*, lead into tubes which are branched, and are called *tracheæ*. These air-tubes are composed of a delicate membrane, which is supported on a series of delicate rings, which are easily traced into the more minute branches. They are well seen in the larvæ of most of the lepidopterous insects, and represented from a caterpillar in figure 222, plate 8. The spiracle is not an open hole. In the common house-fly, seen at figure 212, plate 7. and the water-beetle (*Dyticus*), in figure 213, it is covered over with irregular branched processes from the sides of the opening. The object of this obstruction is probably to prevent particles of dust, and other foreign substances, from entering the air-passages, and thus choking the animal.

The legs of insects will afford an almost unlimited supply of objects for examination. The spoilt specimens of a summer's capture may well supply materials for a winter's examination. The legs of insects are composed generally of five parts, jointed together. The lowest of these is called the *tarsus*, or foot. It is variously formed to adapt it

to the locomotive habits of the insect. In the common fly it is terminated with a pair of disks, which are covered with suckers, called *pulvilli*. Those of the *Empis*, a species of fly, are drawn at figure 198, plate 7. By means of these suckers the animal is enabled to lay hold of smooth surfaces, and thus to crawl up them. They also exude a glutinous matter, which assists in this process. The same kind of arrangement is observed in the common bee, represented in figure 206. The feet are also covered with hairs, and are frequently supplied with hooked joints, which assist the animals in laying hold of rough objects where their suckers would be of no use. In the spider there are no suckers, but the hooked joints and hairs enable the creature to crawl with facility. These hooks are seen in the foot of the spider in figure 207, plate 7. In the *Dyticus* the fore leg is supplied with two large suckers, which are seen in figure 218, plate 8, besides a number of smaller ones, and a hook; whilst the foot of the middle leg is destitute of the large suckers, as seen at figure 219.

The legs of beetles are often covered with little cushion-like bodies, which undoubtedly act as suckers. These are seen at figures 215, 216, 217. The three legs often differ very much from each other, and probably perform modified functions, according to their structure. This is well seen in the legs of the whirligig-beetle (*Gyrinus natator*), in which the first leg, in figure 215, is very much elongated, whilst the third is broad and short, as at figure 217, and adapted for swimming, from its oar-like form. The second leg, seen at figure 216, is intermediate in form and size.

As a contrast to these legs, adapted for the varied functions of the perfect insect, the leg of any common caterpillar may be examined; when it

will be found to consist, at its extremity, of a little sac surmounted with hooks. These hooks are represented in figure 223, plate 8.

The wings of insects, too, are beautiful objects ; easily investigated by a low power. The nerves which run through them are supplied with tracheæ, and they thus become organs of respiration. The under wing of the bee is supplied with a series of hooks, seen at figure 211, plate 7, which slide on a thickened nerve on the upper wing, marked *a*, and keep the wings steady during flight.

The *lepidopterous* insects, including the butterflies and moths, have got their name from the scales on their wings. These scales assume a wonderful variety of form, and claim a large amount of attention from the microscopic observer, and cannot be neglected by the entomologist.

The little blue argus butterfly has scales in the shape of a battledore, drawn at figure 225, plate 8, the handle being the part attached to the wing. All the scales have handles of this sort, whatever be their shape. At figure 226, a scale of ordinary shape is represented. Sometimes the scale is broad at the base, and pointed at top. In the meadow-brown butterfly, the point is surmounted with little clubbed projections, drawn at figure 227. Scales are found on other insects besides moths and butterflies : thus they are found on the common gnat. These are shown at figure 228. Besides their curious forms, the scales are marked with lines which are exceedingly delicate, and require the highest powers of the Microscope to bring them out. Some of the scales are thus used as tests for the powers of the Microscope.

Just as we have seen in the tongues and legs of insects, the same parts expanded or compressed according to the wants of the animal, so we find the

scales assuming various forms. The scales stand in exactly the same relation to the hairs in insects, that the scales of fishes and reptiles do to the feathers of birds and the hairs of mammals. Hair-like scales are therefore not uncommon. At figures 229 and 230, such scales are represented, and may be found on the common clothes-moth.

The young microscopist, for whom our book is written, and with which we hope to make him dissatisfied, in order to facilitate his progress in natural history inquiries, will not spend much time in making dissections. Should he wish to do so, he will find the structure of insects full of interest. He has only to open a cockroach to see how curiously their digestive apparatus is constructed. This insect has a gizzard, and at the upper part it is beset with six conical teeth, as seen at *a*, in figure 220, plate 8; these teeth, working together, reduce its food to a pulvaceous mass previous to digestion. When cut open, their position and relations can be easily seen, as figured at *a*. The gizzard of the cricket is also supplied with teeth, seen at *a*, figure 221; it has three longitudinal series of teeth, and each row in each series contains seven teeth. The family of insects to which the cricket belongs (*Orthoptera*) affords several other instances of the same kind of structure in the gizzard. It will be interesting to compare these teeth of the insects with those of the mollusca and the wheel animalcules.

We must satisfy ourselves with having shown the student the way to cultivate a large field of interesting and instructive phenomena in the insect world, without going further into detail.

The tissues or textures of which animals are built up or made may be easily procured in-doors. We have spoken of the hard parts which form the

outer skeleton of the lower animals, as the molluscs, crabs, and fishes; the internal skeleton of the higher animals affords a not less interesting field of research. If we take a piece of bone, and having ground it so fine that we may examine it with transmitted light under the Microscope, we shall find it composed of a number of minute insect-shaped cells, surrounding an open canal, as seen at figure 232, plate 8. These cells, which are called *lacunæ*, and their little branches *canaliculi*, are modifications of the cells found in fishes' scales, and figured at 175, plate 6.

These curiously-shaped cells differ in size and form in the various classes of animals belonging to the sub-kingdom *Vertebrata*, and thus a small portion of a bone will frequently serve to indicate whether an animal belonged to fishes, reptiles, birds, or mammals. This is a matter of importance to the geologist in determining the character of the inhabitants of the earth at former periods of its history. A section of whalebone is figured at 242, plate 8.

The shells of eggs seems to be formed on the same general principles as other hard parts, and the tendency to the formation of cells with *canaliculi* may be easily observed, as in the section of a common egg-shell, represented at figure 181, plate 6. The young egg-shell should be examined, a section of which is seen at *a*, if the object is to study the history of the development of the shell; and this may be compared on the one hand with the shells of the *Mollusca* and the *Crustacea*, and on the other hand with those of the scales, teeth, and bones of the vertebrate animals. Egg-shells present very different appearances. The shell of the emu, for instance, exhibits a series of dark triangular spots, and is represented at figure 183, plate 6.

As one of the hard parts of animals, the structure of cartilage is very interesting. A slice may be obtained from the gristle of any young animal. Its structure is best seen in the mouse's ear, represented at figure 231, plate 8. No one who looks at this object can but be struck with its resemblance to vegetable tissue; and it was this resemblance which led to the application of the cell theory of development, which had been made out in vegetable structures, to those of animals.

Many of the soft parts of animal tissues afford instructive objects under the Microscope. If the tongue is scraped, and a drop of the saliva thus procured placed under the Microscope, it will be found to contain many flat, irregular, scale-like bodies with a nucleus in the centre, such as are seen at figure 4, plate 1. These scales are flattened cells, and closely resemble those found on the surface of the skin. Cells of a different kind line the air-passages. If a snip be taken from inside the nostril of a recently killed ox or sheep, it will be found to be composed of cells which are fringed with cilia at the top. These are seen at Figure 5, Plate 1. These cilia are constantly moving, and produce the motion of the mucus on the surface of these passages which is essential to their healthy action.

The blood of animals presents us with objects of high interest. The human blood consists of a liquid in which float two kinds of cells. They are discoid bodies, from the three-thousandth to the three-thousand-five-hundredth of an inch in diameter ($\frac{1}{3000}$ to $\frac{1}{3500}$), and about a fourth of that size in thickness. They are represented at figure 6, plate 1. They are of two sorts—pale and red; the latter are rather smaller, but are by far the most abundant. They present a little spot in the centre,

which is called a *nucleus*, and this again another little spot, which is called a *nucleolus*. The red globules vary much in size and form in different animals. Thus, in birds, reptiles, and fishes, they are oval instead of round ; and, mostly, in these three classes much larger than in mammals. This is especially the case in the *batrachian* reptiles, to which the frog and toad belong. Those from the frog are shown at figure 8, plate 1. In the fowl, shown at figure 7, and in the sole, seen at figure 9, they are nearly twice as large as in man. In the insects they are also frequently of large size, as in the cockchafer, seen at figure 10.

The proof that blood-stains have been produced by human blood on articles of dress and other things, is frequently important in medico-legal investigations. Although it cannot be distinguished from all other kinds of blood, it may be from some ; and the Microscope has been employed as an adjunct in such cases.

The structure of the skin, and other organs of the body, are very interesting subjects for microscopical investigation ; and volumes have been written upon their diversified details. The structure of voluntary and involuntary muscular tissue may be easily examined, especially the former, by taking a portion of the flesh of any animal usually eaten as food. The striated fibrillæ of voluntary muscle may be best seen in flesh cooked as food. A muscle consists of bundles of fibres, and each of these fibres consists of several fibrillæ lying close together. Each of these fibrils is seen to be crossed with lines, represented in figure 233. plate 8. These lines indicate the point of union of the string of cells which form the ultimate parts of the muscular tissue.

The structure of nervous tissue is also one of

high interest to the physiologist, but it requires the highest powers of the Microscope, and great skill in manipulation, to make out.

We must now, however, draw our last half hour to a close. All we have attempted has been in the way of introduction. We have only described those things which are most easily obtained, and we have sought rather to create a desire for further knowledge, than to impart an exhaustive amount of information on any one subject.

Those who have properly apprehended our remarks will see that there is not a distinct science of microscopic objects, but that these objects belong to various departments of science, whose great facts and principles must be studied from works devoted to them. The Microscope is in fact an instrument to assist the eyes in the investigation of the facts of structure and function, wherever they may occur in the great field of nature; and that inquirer must have a very limited view of the nature of science, who supposes either that the Microscope is the only instrument of research, or that any investigation, where its aid reveals new facts, can be successfully carried on without it.

APPENDIX.

BY THOMAS KETTERINGHAM.

THE PREPARATION AND MOUNTING OF OBJECTS.

THE majority of objects exhibited by the Microscope require some kind of preparation before they can be satisfactorily shown, or their form and structure properly made out. To convince the beginner of this, let him take the leg of any insect, and, without previous preparation, place it under his Microscope, and what does he see? A dark opaque body, fringed with hair, and exceedingly indistinct. But let him view the same object prepared and permanently mounted, and he will then regard it with delight. That beautiful limb, rendered transparent by the process it has undergone, now lies before him, rich in colour, wonderful in the delicate articulation of its joints, exquisite in its finish, armed at its extremities with two sharp claws equally serviceable for progression or aggression, and furnished, in many instances, with pads (*pulvilli*) (see plate 7, figures 205, 206), which enable the insect to walk with ease and safety on the smoothest surface. If the beginner has a true love for the study of the Microscope, he will be glad of information respecting the method pursued in dissecting and preserving microscopic objects, nor will he rest satisfied until he has acquired some knowledge of the art. We will briefly point out a few of the advantages possessed by those who are able to prepare specimens for themselves.

Objects well mounted will remain uninjured for years, and will continue to retain their colour and structure in all their original freshness.

They can be exhibited at all times to one's friends, and may be studied with advantage whenever an opportunity occurs.

By the practice of dissection such a knowledge is gained of the varied forms and internal organization of minute creatures as can be obtained in no other way.

There are doubtless many who, possessing a small Microscope, are unable by reason of their limited means to expend money in the purchase of ready-prepared specimens. To such, a few plain directions, if followed, will be of service, and will enable them to prepare their own.

The materials necessary for the beginner are few, and not expensive. In fact, the fewer the better; for a multiplicity is apt only to cause confusion. The following will be found sufficient for all ordinary purposes, and may be obtained at any optician's.

Bottle of new Canada balsam.

Bottle of gold-size.

Bottle of Brunswick black.

Spirits of turpentine—small quantity.

Spirits of wine—small quantity.

Solution of caustic potash (*liquor potassæ*).

Ether—a small bottle.

Empty pomatum-pots, with covers, for holding objects while in pickle.

Half a dozen needles mounted in handles of camel-hair brushes.

Pair of brass forceps.

Two small scalpels.

Pair of fine-pointed scissors.

Camel-hair pencils—half a dozen.

Slips of plate-glass, one inch by three inches—two dozen.

Thin glass covers, cut into squares and circles—half an ounce.

We will suppose that the beginner, having purchased the necessary materials, is about to make his first attempt. Let him attend to the following advice, and he will escape many failures.

He must bring to his work a mind cool and collected; hands clean and free from grease. Let him place everything he may require close at hand, or within his reach. A stock of clean slides and covers must always be ready for use. He must keep his needles, scissors, and scalpels scrupulously clean. An ingenious youth will readily construct for himself a box to contain all his tools. Cleanliness is so essential to success, that too much stress cannot be laid upon it. All fluids should be filtered and kept in well-corked phials. A bell-glass, which may be purchased for a few pence, will be found exceedingly useful in covering an object when any delay

takes place in the mounting. For want of it, many specimens have been spoilt by the intrusion of particles of dust, soot, and other foreign substances. Let the table on which the operator is at work be steady, and placed in a good light, and, if possible, in a room free from intrusion.

WINGS OF INSECTS.—Perhaps these are the easiest objects upon which the beginner can try his “prentice hand.” Here little skill is required. Select a bee, or wasp, and with your fine scissors sever the wing from its body; wash it with a camel-hair brush in some warm water, and place it between two slips of glass, previously cleaned, which may be pressed together by a letter-clip, or an American clothes-peg; place it in a warm corner for a few days; when *quite dry*, remove it from between the slides, and soak it for a short time in spirits of turpentine. This fluid renders the object more transparent, frees it from air-bubbles, and prepares the way for a readier access of the balsam to the various portions of its structure.

Having selected from your stock a clean slide of the requisite size, and a thin glass cover somewhat larger than the object about to be mounted, hold them both up to the light, when any slight impurities will appear, and may be speedily removed by rubbing the surfaces of the glass with a fine cambric handkerchief, or a piece of soft wash-leather. Should, however, a speck or flaw in the glass itself be found in the centre of the slide, at once reject it and choose another. Remove the wing with a pair of forceps from the turpentine, and place it in the exact centre of the slide: this may be accomplished by cutting a stiff piece of cardboard, tin, or zinc, the size of the slide, and punching a hole, the edge of which should be equally distant from each end and each side; lay the slide upon it, and place the object in the circular space; you will thus get it properly centred.

Before dropping the balsam (which should have been previously warmed) upon the specimen, place it under the Microscope: you may possibly detect some foreign substance, in the shape of a particle of soot or a fibre from your handkerchief, in contact with it; remove it with the point of a needle. Take up a small quantity of the balsam on the end of a small glass rod, and let it fall upon the object; hold the slide for a few minutes over the flame of a candle or spirit-lamp at a distance sufficient to make it warm, but not hot; the balsam will gradually spread itself over and around the object: should air-bubbles arise, they may be broken by touching them with the point of a needle; they will, how-

ever, frequently disperse of themselves as the balsam dries. The thin glass cover, being warmed, should now be placed upon the object, and a slight pressure applied to get rid of the superfluous balsam. Place the slide in some warm spot to dry; an oven will do very well, if the fire has been some time removed and there is not sufficient heat to make the balsam boil.

In a short time the balsam round the edges of the cover will be hard enough to admit of the greater part being scraped off with a knife; the remainder may be got rid of by wiping the slide with a rag dipped in turpentine or ether. The finishing touch consists in labelling the object with its proper name. It will be found advantageous to place the common name of the specimen at one end of the slide, and its scientific name at the other.

Some persons prefer covering their slides with orramental paper, which may be obtained of almost any optician. Others prefer the glass without any covering at all. In the latter case the edges of the slide should be ground, the round thin glass covers used, and the name scratched upon the slide with a writing diamond. In the former, the edges of the slide, being covered with paper, need not be ground, but square thin covers should be used instead of round ones, and the name written with pen and ink in the square places allotted at each end of the slide.

LEGS OF INSECTS (plate 7, figures 205, 206, 207; plate 8, figures 215 to 219, 223, 224).—These require a little more preparation than wings; and as they possess some thickness, and are mostly opaque, besides being of a hard, horny character, they should be placed for a fortnight, or even longer, in *liquor potassæ*; this will soften the tissue and dissolve the muscles and other matter contained within them, so that by gently pressing the limb between two slips of glass, the interior substance will gradually escape, and may be removed by repeated washings. The squeezing process, however, must be conducted gently, to prevent any rupture: perhaps the best plan is to plunge the slips of glass into a basin of clean water, when all impurities oozing out from the pressure will sink to the bottom. Should the leg not be sufficiently softened to be squeezed quite flat, it must be again placed in the solution for a longer period, until this result be obtained. On removing it from the potash, it should be well washed with a camel-hair pencil in clean water, placed between two slips, held together by an American clothes-peg with a good stiff

spring. If placed in a warm corner, a few days will be sufficient to dry it thoroughly : afterwards soak it in spirits of turpentine ; the time of immersion to be regulated by the opacity of the object.

The directions for mounting in balsam are precisely the same as those given for the wings of insects. Care should be taken not to heat the balsam too hot, as it will invariably destroy delicate specimens by curling them up. In tough horny structures, such as the wing cases of beetles, &c., heat is sometimes an advantage, and there are a few structures that show to advantage when the balsam has been heated to a boiling pitch ; but for the majority of objects, a gentle warmth is all that is required.

OVIPOSITORS AND STINGS (plate 7, figure 200) are more difficult to prepare, and require some amount of dissection before they can be properly displayed. To do this, some degree of skill is necessary, and a knowledge of insect anatomy, which can be acquired only by study and practice. As a rule, all dissections should be carried on as far as possible with the naked eye ; when this has been accomplished, we must then seek the aid of lenses.

The object-glasses of one's Microscope are the best that can be used for the purpose. An inch lens will be found especially fitted for the work. A simple Microscope, provided with a broad stage, and an arm movable by rack and pinion, for carrying the lenses, is the kind of instrument usually employed. It should be strongly made, and capable of bearing a good deal of rough usage.

Dissections may be carried on under the compound Microscope ; but we do not think the beginner would succeed, as objects become inverted and motion reversed when seen through this instrument. If, however, it be provided with an erector, this difficulty is overcome by the object being brought into the same position that it occupies when seen by the naked eye.

As most dissections are carried on under water, some kind of shallow trough is necessary to contain it : watch glasses answer the purpose remarkably well. The small white dishes and covers used for rubbing up colours will be found very useful ; also some cork bugs on which to pin the object ; and these last should have their under sides loaded with lead to sink them in fluid. A great many delicate dissections may, however, be made in a drop of water placed on a slip of glass ; but for all objects of large size, the trough, or some similar contrivance, will be necessary.

All insects that have been killed a long time, and whose bodies are hard and brittle, may be softened by immersing them in the solution already mentioned.

The sting of the bee, wasp, hornet, and the ovipositors of many flies, especially the ichneumons, are very similar in their structure, and are generally found at the termination of the abdomen, from which they may be obtained by first slitting open the body of the insect with the fine scissors, and afterwards removing the sting by using the scalpel and needles. One or two of the latter should have their points curved, which may easily be accomplished by heating the ends red-hot in the flame of a candle, and bending them with a pair of small pincers. At first sight the sting presents nothing to the eye but a horny sheath, tapering to a point, with a slit broadest at its base and running down the entire length; within this sheath, on each side, lies a barbed, sharp-pointed spear, in large insects capable of inflicting a severe wound, while the tube in which they are lodged acts as a steady rod, and as a channel to conduct a virulent poison to the wound. The bag containing the poison is placed at the root of the sting, and is connected by a narrow neck with the sheath. The difficulty in the dissection of the sting lies in getting the barbed points out of the sheath and placing them on each side of it. The following is the method employed by the writer. The sting is placed in potash until it loses some of its rigidity; it is then transferred to a slip of glass or earthenware trough. The curved needle-points are essential here. With one, hold the object firmly on the stage of the Microscope, insert the point of the other into the opening at the base of the sheath where it is largest, and gradually draw the point down the tube; this will make the opening wider, and dislodge the barbs; arrange them on each side of the sheath, place the sting between two glass slips subject to pressure. When dry, soak it for a few days in turpentine, and mount in balsam in the usual manner. A good specimen ought to show the barbs very distinctly on each side of the sheath.

It will be found useful to the student to prepare three specimens of this organ:—

1st. The whole abdomen, showing the position the sting occupies within it.

2nd. The sting with the barbs lying within the sheath.

3rd. The barbs pulled out of the sheath and placed on each side of it.

Three such specimens well mounted will enable the student

to study the structure of this curious organ with advantage.

SPIRACLES (plate 7, figures 212, 213).—These do not require much dissection. They are generally found on each side of the abdomen, almost every segment of which possesses a pair. Excellent specimens are furnished by the dytiscus, bee, blowfly, cockchafer, and silkworm. To prepare them, separate from the thorax the abdominal portion of the insect, and slit it down the centre with the fine-pointed scissors, draw out the viscera, &c., with the curved needles. The air-tubes adhering to the spiracles may be detached by cutting them away with the scissors. Thoroughly cleanse the horny cuticle by repeated washings, spread it out flat between two slips of glass; when dry, immerse it in spirits of wine or turpentine for a few days, and mount it in balsam. In this manner the whole of the spiracles of an insect, running down each side of the abdomen, will be displayed.

TRACHEE (plate 8, figure 222).—The best method we are acquainted with for obtaining the air-tubes of insects is that recommended by Professor Quekett:—

“By far the most simple method of procuring a perfect system of tracheal tubes from the larva of an insect, is to make a small opening in its body, and then to place it in strong acetic acid: this will soften or decompose all the viscera, and the tracheæ may then be well washed with the syringe, and removed from the body with the greatest facility, by cutting away the connections of the main tubes with the spiracles by means of the fine-pointed scissors. In order to get them upon the slide, this must be put into the fluid and the tracheæ floated upon it, after which they may be laid out in their proper position, then dried, and mounted in balsam.”

The best specimens are found in the larva of the dytiscus and cockchafer, and in the blowfly, goat-moth, silkworm, and house-cricket.

GIZZARDS (plate 8, figures 220, *a, b*; 221, *a, b*).—Most of the insects from which these organs are procured being of large size, it will be necessary to secure them to one of the loaded corks by small pins. The dissection should be made in one of the shallow troughs, filled with weak spirits and water. Cut the insect open; the stomach will float out with the gizzard attached to it, in the shape of a small bulbous expansion of the size of a pea. Insert the fine point of the scissors, and cut it open; the interior will be found full of food in process of trituration. Empty the contents of the gizzard, and wash it out well; place it for

a few days in the solution of potash : and, finally, cleanse it with some warm water and a camel-hair brush. Spread it out flat between slips of glass ; when dry, place it in turpentine for a week, and afterwards mount it in balsam.

The best specimens for displaying the horny teeth with which the gizzard is furnished are obtained from crickets, grasshoppers, and cockroaches.

PALATES (plate 6, figures 171, 172, 173, 174). — These consist of a narrow kind of tongue, armed with a series of horny teeth, placed in regular rows. The whelk, limpet, periwinkle, garden-snail, and the snails found in our cellars and aquariums, are all furnished with this peculiar apparatus, which may be obtained by laying open the body with the scalpel or scissors. It will generally be found curled up near the head, and may be distinguished by its ribbon-like appearance : patience and skill are necessary to extract it from the surrounding mass. When properly cleaned, it may be at once pressed flat and dried between slips of glass. Many palates polarize well when mounted in balsam ; but if not intended for polarization, they should be mounted in a preservative fluid, composed of five grains of salt to one ounce of water.

TONGUES, PROBOSCES, MANDIBLES, AND ANTENNE (plate 7, figures 197, 199, 202 to 204) are amongst the most beautiful objects exhibited by the Microscope. Many of these, besides the ligula, possess several sharp lancets for puncturing the skin of animals from whom they derive their sustenance. To arrange these organs so that each part may be clearly seen, requires a good deal of delicate manipulation. It is generally more satisfactory to mount the whole head of the insect. To accomplish this, it must be softened by immersion in *liquor potassæ* for some time, and the interior substance got rid of by pressure. To dry it flat, place it between two slips of glass, which should be held together by a spring-clip ; soak it for a fortnight or longer in turpentine, until it becomes transparent, and then mount it in balsam.

The head of the bee, wasp, dronefly, blowfly, and gadfly, are all excellent examples of the varied structures of these suctorial organs.

EYES (plate 7, figures 208, 208a, 216). — The compound eyes of insects, for the display of their numerous facets, should be dissected from the head, and macerated in fluid. The black pigment lining the interior may be got rid of by washing it away with a camel-hair brush. When quite

clean, the cornea may be dried and flattened between two slips of glass. In practice, however, the cornea, from its sphericity, will be found to have a tendency to fold in plaits, or to split in halves. To remedy this, cut with the fine scissors a few notches round its edges; it may then be flattened without danger of its either wrinkling or splitting. When the cornea is very transparent it should be mounted in a cell with some kind of preservative fluid (spirit and water will do very well), otherwise the structure will be lost if mounted in balsam, the tendency of that substance being to add transparency to every object with which it comes in contact. But there are many insects in whose eyes the hexagonal facets are strongly marked: all such will show best when mounted in balsam.

HAIRS (plate 7, figures 181 to 191). These may be mounted either in fluid or balsam, first taking the precaution to cleanse them from fatty matter by placing them in ether. If the hair be coarse and opaque, mount it in balsam; if fine and transparent, it should be mounted in a cell, with some weak spirit.

Sections of hair are made by gluing hairs into a bundle, and placing it in a machine for making sections. By means of a sharp knife which traverses the surface, the thinnest slices may be cut, and each individual section afterwards can be separated in fluid. To select the thinnest and best, place them under the Microscope. The point of a camel hair pencil will be found the best instrument for transferring them to a clean slide. When dry, mount them in balsam, as usual. Some very good sections of the hairs of the beard may be obtained by passing the razor over the face a few minutes after having shaved.

SCALES OF FISH (plate 6, figures 178 to 180).—These dermal appendages may be detached from the skin by a knife; and if to be viewed as opaque objects, may be dried and mounted with no other preparation than cementing over them a thin glass cover. If intended to be viewed as transparent objects, the scales should be properly cleaned, dried, and mounted in balsam; but the most satisfactory way of exhibiting their structure is to mount them in a cell with some preservative fluid.

SCALES OF BUTTERFLIES, MOTHS, &c. (plate 8, figures 225 to 229).—Select the wing of a living or recently-killed insect, gently press it on the centre of a clean glass slide. On removing the wing, numerous scales will be seen adhering to the slide; place over them one of the thin glass covers, and cement it down by tipping lightly the edges with gold size.

Specimens should be taken from various parts of the wings of the same insect, as the form of the scales vary according to the position they occupy in the wing.

SECTIONS OF BONE (plate 8, figure 232).—All hard and brittle substances from which thin slices cannot be made by a sharp knife, must be reduced to a transparent thinness by the process of grinding down. Having selected the bone from which the section is about to be made, a thin slice should be cut from it with a fine saw. At first the section may be held by the fingers while grinding down one of its surfaces on a coarse stone; but when it approaches the thinness of a shilling, it must be cemented by some old and tough Canada balsam to a slip of glass. Upon the perfect adhesion of the section to the slide depends in a great measure the success of the operation. Having reduced the thickness of the section by a coarse stone or a file, transfer it to a hone; a few turns will obliterate scratches, and produce an even, smooth surface, which may be further polished by rubbing it on a buff-leather strop charged with putty-powder and water. When dry, attach the polished surface to the glass slip: this gives a firm hold of the section, which would otherwise become too thin to be held by the fingers. In rubbing down the unfinished surface, take care that an equal thickness prevails throughout the section. As it approaches completion, recourse must be frequently had to the Microscope, in order to determine how much further it is necessary to proceed, a few turns either way at this stage being sufficient to make or mar the specimen. When it has become so transparent that objects may be readily seen through it, remove it from the hone and polish it on the strop. To detach it from the slide when finished, place it in turpentine or ether, both being excellent solvents of balsam. Mount in the dry method, by simply cementing a thin glass cover over it. In recent bone, this method of mounting, though the most difficult, is decidedly the best for displaying its structure. Fossil bone, however, where the interstices are filled with earthy matter, shows best in balsam.

SPINES OF THE ECHINUS (plate 5, figures 151, 152); SECTIONS OF SHELL (plate 6, figures 165 to 169).—These are cut and reduced in the same manner as sections of bone; but they require greater care in grinding, in consequence of being more brittle. The polishing, however, may be dispensed with, and the section mounted in balsam.

STONES OF VARIOUS KINDS OF FRUITS (plate 8, figure 243) will well repay the labour bestowed in producing good sections. The saw, the file, and the hone are the principal

agents used in the reduction of these hard osseous-like tissues. A perfect section should have but one layer of cells, which may be admirably seen when mounted in a cell with weak spirit.

SECTIONS OF WOOD (plate 3, figures 54 to 59).—To make thin sections of hard wood it will be necessary to employ some kind of cutting machine. There are several of these, more or less expensive, but the principle of construction in all is similar. The wood, after some preparation, and being cut to the requisite length, is driven by a mallet into a brass cylinder, at the bottom of which works a fine screw with a milled head. The wood is pushed to the surface of the tube, and to any degree above it by the revolution of the screw; when a sharp knife, ground flat on one side, is brought with a sliding motion in contact with it. The slices may be removed from the knife by a wetted camel-hair pencil, placed in some weak spirit, and examined at leisure; the thinnest and most perfect section being retained for mounting. Green wood previous to being cut should be placed in alcohol and afterwards in water. Hard and dry wood may be made sufficiently soft for slicing by first immersing it in water for some days. Sections of the above may be mounted either in balsam or fluids. Stems of plants, horny tissues, and many other substances not sufficiently hard to be ground down, may be cut into slices of extreme thinness by this handy instrument. In order to obtain a correct idea of the structure of wood, bone, and shell, sections should be made in vertical, transverse, and oblique directions.

CUTICLE OF PLANTS (plate 2, figures 42 to 46), HAIRS (plate 3, figures 74 to 88), AND SPIRAL VESSELS (plate 2, figures 47 to 49), may all be obtained by macerating the leaves and stems of plants in water, and afterwards dissecting them with the needles. Good specimens of the cuticle, showing the stomata, may be often obtained by simply peeling off the skin with a sharp knife. Hairs may be detached from various parts of a plant by a similar process. Spiral vessels will, however, require to be separated by the needles from the surrounding tissues. All delicate vegetable preparations are best displayed when mounted in a cell with weak spirit.

Cells for mounting objects in fluid are generally formed of some kind of varnish upon which the fluid will not act; gold-size and Brunswick black are most commonly used. To form a cell, simply charge a camel-hair brush with the varnish, and enclose with a broad black ring a small circular space on the centre of the slide. When quite dry, it is ready

for use. Place the object, with a small quantity of fluid, in the cell ; and having lightly touched the edges of the thin glass cover with gold-size, drop it gently on the specimen ; the superfluous fluid will escape over the sides of the cell, and may be removed by small pieces of blotting-paper, taking care, however, that none of the fluid is drawn from the interior of the cell ; in which case an air-bubble would immediately appear. To make the cell air-tight, gradually fill up the angle formed by the edges of the cover with the cell, by running several rims of varnish round it. In order to prevent the cement from running into the cell and spoiling the specimen, each layer should be dry before another is placed upon it.

The student should always have a stock of cells on hand ready for immediate use. Dozens of these cells may be made in half an hour by an ingenious little turntable, the invention of Mr. Shadbolt, and which may be obtained for a few shillings.

The limits of this little work have precluded us from giving little more than general directions respecting the permanent preparation of microscopic objects. Our object has been merely to give a few plain instructions, which, if carefully followed, will enable the beginner to prepare some of the most popular objects exhibited by the Microscope.
